Bacteriophages are viruses whose hosts are bacteria. Bacteriophages are the most numerous and genomically diverse form of life in the environment. Many bacteriophage genes have either (1) no detectable homology to any other bacteriophage/cellular gene or (2) homology to extremely diverged bacteriophage genes of presumably similar function. When infecting a host bacterial cell, a double-stranded DNA bacteriophage produces proteins that package progeny DNA genomes in a protein container (capsid) that protects its genome when the bacteriophage is outside of a cell. The energy requirement for DNA packaging is approximately 0.5 kcal mol^{-1} of packaged nucleotide pair. The capsid and accessory proteins join to form an ATP-fueled motor that drives the DNA molecule into a cavity in the capsid. The motor packages the DNA molecule via end-first motion through a portal ring also called *the connector*. An accessory protein/ATPase is at least the spark plug of the motor. Bacteriophage DNA packaging motors are investigated as a prototype for understanding other biological motors. Testing for feedback control of the motor is an important current objective. Investigations of both bacteriophage DNA packaging and bacteriophage capsid assembly have produced *in vitro* systems that are complex. One strategy for analysis of such complex systems is observation at the level of single events (single-particle analysis). Single-particle analysis has already revealed surprising cooperativity among DNA packaging events and has also revealed a comparatively strong motor capable of generating about 40 to 70 pN of force while intermittently hesitating. Bacteriophage DNA packaging systems are useful for further developing procedures for single-particle analysis of complex biochemical systems.

1 Biology of Bacteriophages: DNA Packaging

Bacteria (and Archaea) are single cells without a nucleus that can live independently. Bacteria are found almost everywhere, even in environments of extreme high and low temperature. Bacteria have parasites that are smaller than cells. These parasites typically consist of a protein shell (capsid) that has an internal cavity in which a nucleic acid molecule is packaged. Although both RNA-containing and single-stranded DNA-containing bacteriophages have been isolated, the nucleic acid is usually (96% of current isolates) a double-stranded DNA molecule. These subcellular

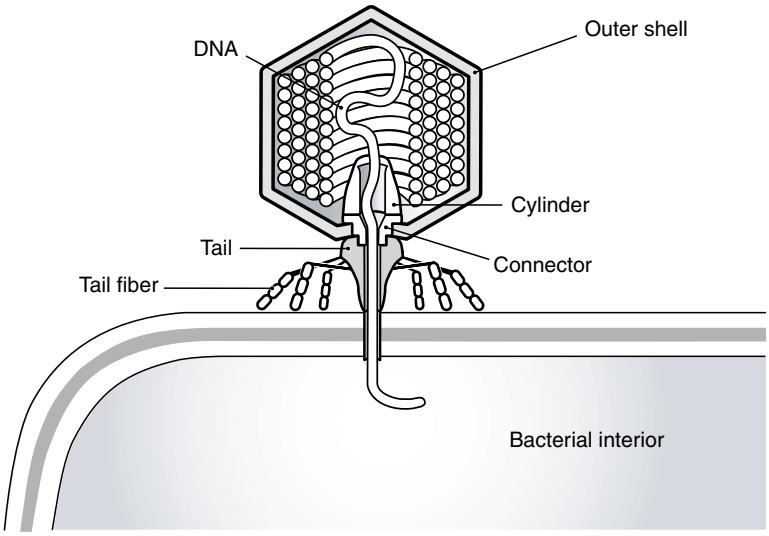

Fig. 1 Infection of a host cell (only partially shown) by a single particle of bacteriophage T7.

parasites are called *bacteriophages*. The capsid of a double-stranded DNA bacteriophage has an external projection (tail) that has fibers for attachment of the bacteriophage particle to a host cell. After attachment, a double-stranded DNA bacteriophage injects its DNA genome into the host cell. This process is illustrated in Fig. 1.

After the DNA genome is injected, it sometimes initiates production of progeny bacteriophages, typically over 100 per cell. The progeny bacteriophages are released when the cell bursts (lyses). This process is called *lytic infection*. Alternatively, the injected genome can become part of the cell's genome (prophage), sometimes by physically incorporating itself into a bacterial chromosome. In this latter case, the state of the bacteriophage chromosome is called *lysogenic* because of the capacity to reinitiate a lytic cycle at a later time. This latter life cycle is called *temperate*. Thus, bacteriophages can either destroy bacterial cells (lytic bacteriophage) or coinhabit bacterial cells (lysogenic bacteriophage). Lysogenic bacteriophages sometimes acquire exogenous genes and transfer them to the host genome. Investigators can make deliberate use of both lytic and gene-transferring functions.

A lytic infection produces progeny double-stranded DNA bacteriophages via the following route: (1) A nucleic acid-free capsid (procapsid) is assembled. (2) Then, the procapsid binds a DNA molecule. (3) Next, the procapsid draws the DNA molecule into its internal cavity through a 12-fold symmetric ring called *a connector*. This process is called *DNA packaging*. The driving force for DNA packaging is derived from a noncapsid accessory protein that attaches to the connector. This protein is the larger of two accessory proteins that are not initially part of the capsid, but attach to it for DNA packaging. The larger accessory protein (also called *the large terminase subunit*) is an ATPase that cleaves ATP to produce energy that is used to package the bacteriophage genome.

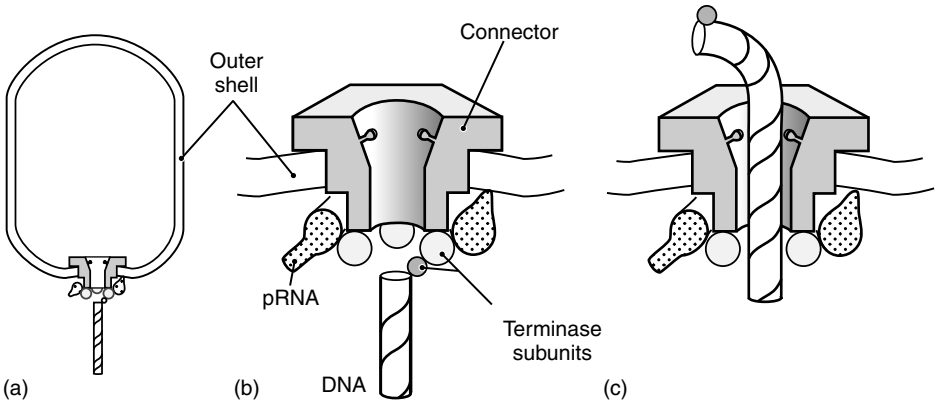

Fig. 2 The bacteriophage ϕ29 DNA packaging motor. (a) The entire ϕ29 procapsid that has initiated DNA packaging by binding a DNA molecule. (b) A magnified view of the DNA-binding region of the same procapsid with connector, terminase subunits, DNA molecule, and also a packaging RNA molecule (pRNA) that is part of the motor. (c) The same as the view of (b), but after the DNA molecule has started to enter the internal cavity of the capsid. The pRNA molecule has thus far been unique to bacteriophage ϕ29.

Typically, six large terminase molecules are present during DNA packaging. The process of DNA packaging is shown schematically in Fig. 2 for bacteriophage ϕ29. The capsid with accessory proteins is called the *DNA packaging motor*. DNA packaging motors are studied not only to understand bacteriophages but also to understand biological motors in general.

1.1 Microbe Hunting

Bacteriophages originate in the environment. So far, all double-stranded DNA bacteriophages have packaged their genome via a procapsid with an ATPase/large terminase subunit that formed at least the ''spark plug'' of the DNA packaging motor. The large terminase proteins from widely different bacteriophage genomes have either no or barely detectable sequence similarity. However, biochemical similarities among the characterized large terminases are explained with the assumption of descent from a single ancestral gene, followed by divergence. Thus, comparison at the level of secondary and tertiary structure is potentially useful for analysis of both the biochemical mechanisms and the evolution of DNA packaging genes. To fill the evolutionary tree of bacteriophage genes, a more comprehensive collection of bacteriophages is sought. This collection will also be useful for the practical purposes of (1) bacteriophage therapy, the use of bacteriophages for controlling/eliminating unwanted bacteria, and (2) bacterial transduction, the use of bacteriophages to introduce new properties to bacteria.

No doubt, researchers have much to do before they obtain a representative sample of environmental bacteriophages. Environmental water typically has 10s of billions of bacteriophages particles per liter and soil typically has 100s of billions of bacteriophages particles per pound. The number of strains is typically smaller, but is still considered very large, especially since very

few (none in some cases) of these bacteriophages are currently cultured. To compound this lack of knowledge, less than 1% of all strains of visible bacteria have been cultured. Thus, the art of microbe hunting is becoming important again, as it was 100–150 years ago. In the previous era of microbe hunts, success in culture was usually associated with success in identifying a component of bacterial nutrition. Perhaps, success in today's microbe culturing-based hunts will be associated with success in identifying other details of microbial life, for example, the need for either a solid surface or another niche in which a microbe is competitive. Some of the current hunts are performed by polymerase chain reaction amplification of environmental DNA, that is, without culturing the bacteriophage. Similarly, some hunts are performed by shotgun cloning/sequencing of environmental bacteriophage DNA, again without culturing.

1.2 Bacteriophage Genomics, Proteomics, and Informatics

In the 1960s–1980s, researchers investigated both bacteriophage genome organization and bacteriophage gene functions either by (1) mutating and mapping the various bacteriophage genes, or (2) by observing the biochemical changes that occurred during infection. The biochemical changes include production of messenger RNA and proteins, for example. Sometimes these two strategies were combined. For example, the various genes were deliberately given mutations that produced premature polypeptide chain termination when a mutant bacteriophage was grown in a nonpermissive host. The protein encoded by a mutated gene was deduced by observing which protein was shortened. The length of any given protein was determined by electrophoretic fractionation through a polyacrylamide gel, after homogenizing the electrical surface charge density of all proteins by boiling them in sodium dodecylsulfate(SDS) (SDS polyacrylamide gel electrophoresis, or SDSPAGE).

These early investigations of genetics and biochemistry identified the signals for both starting and stopping the production of both messenger RNA (transcription) and messenger RNA-encoded proteins (translation). Most sequenced bacteriophages are now initially characterized by computer-based recognition of these features. The current state of the art is that excellent predictions are made for large proteins and for major transcriptional start sites. Predictions for small proteins are often unreliable.

The expanded informatics also recognizes homology among the coding sequences of genes of both bacteriophages and prophages. Detection of conserved protein sequences is a means for determining whether a protein of significant function is, in fact, made. A steady stream of new bacteriophage gene sequences is helping the finding of additional genes. Nonetheless, about half of all prospective bacteriophage genes have no detected relative.

Furthermore, studies of homology have found extreme divergence among bacteriophages in the sequence of a gene for any given function. The gene for the large terminase subunit is an example. Evidence for lateral DNA transfer among bacteriophages has been found. The lateral transfer occurs for DNA segments that vary in span from a partial gene to a module that comprises several genes. The result is mosaicism in the pedigrees of bacteriophage

genomes. The implied common gene pool is accessed by multiple bacteriophages that do not have a known common host.

The variability and plasticity of any given bacteriophage gene is a potential subject for informatics-based correlation of biochemical characteristics with structural characteristics. For example, the informatics has identified a P-loop ATPase site near the N-terminus of the large terminase subunit of all studied double-stranded DNA bacteriophages. Genetic interference with the integrity of the P-loop causes either loss or slowing of DNA packaging activity for at least two bacteriophages (λ and T3). Thus, the assumption is made that this ATPase is the site of the "spark plug"of the DNA packaging motor. Furthermore, we expect differences among the large terminases because (1) the terminase is involved in the initiation of DNA packaging and (2) differences exist in the DNA substrate for packaging. Some substrates are DNA circles; some are linear polymers of the mature genome, and, therefore, longer than the mature genome (called *a concatemer*); others (including bacteriophage ϕ29 DNA) are mature, linear genomes with the smaller terminase protein covalently joined to the 5′ ends. Cleavage is part of initiation in the case of both circular and concatemeric genomes. Comparative informatics will hopefully show how the large terminase adapts to a change in DNA substrate for packaging.

Today, the DNA sequence of a newly isolated bacteriophage is determined directly by use of a combination of shotgun cloning/sequencing and direct sequencing of the bacteriophage DNA. The proteins produced by the bacteriophage can now be analyzed by a combination of SDSPAGE and mass spectroscopy. This technology is expected to reduce uncertainty about which prospective genes are actually expressed. Additionally, the occurrence of posttranslational changes, such as protein fusion and cleavage, will be directly analyzed when this type of protein analysis is combined with the DNA sequence.

2
Physical Chemistry of DNA Packaging

2.1
Energy of Compaction

While some investigators focus on bacteriophage biology, others focus on the physical chemistry. In fact, a primary reason for use of bacteriophages as a model system is the opportunity for interdisciplinary investigation. In the case of DNA packaging, one can calculate the energy needed to compact the DNA to the density found in the capsids of bacteriophages. This density is uniform ±15% among the various bacteriophages. The density of DNA packaging is measured primarily by use of low angle x-ray scattering, but also by use of buoyant density centrifugation in media that minimally dehydrate a packaged DNA molecule. These two measurements agree that the DNA double helix occupies about one half the volume of the cavity in which the DNA is packaged.

Given this number, theoreticians calculate the energy per mole of nucleotide pair needed for (1) overcoming electrostatic repulsion among negatively charged DNA segments, and (2) bending the double helix against elastic forces that originate in both electrostatic repulsion and base stacking. The packaging-associated entropic change makes a negligible contribution to the free energy of DNA compaction. Overcoming the electrostatic repulsion is the

primary energetic requirement for packaging. Experimentally, expulsion of the packaged DNA (without disassembly of the capsid) releases heat that is another indication of the free energy of packaging because the entropy of packaging is negligible. Experiment and theory agree on approximately 0.5 kcal mol^{-1} of packaged nucleotide pair. Both theory and experiment also agree that circular coiling of packaged DNA is the most probable conformation. However, neither theory nor experiment conclusively discriminates between unidirectional coiling (as with thread on a spool) and bidirectional coiling (as rope is sometimes stored on the deck of a ship). Bidirectional coiling would produce kinks. A drawing of the packaged DNA of bacteriophage T7 within its capsid is in Fig. 1. This drawing is based on cryoelectron microscopy of T7.

A third measure of the energy of DNA compaction was achieved by integration of the force times the distance interval of a DNA molecule during its packaging. But, how does one measure the force, especially when the force is expected to increase as more DNA becomes packaged? An answer has recently been provided via the development of procedures for (1) attaching to a large latex sphere both a capsid that is packaging a DNA molecule and the capsid-distal end of the DNA molecule (see Fig. 3a), (2) holding the capsid-distal sphere in an optical trap of known force constant, (3) holding the capsid-bound sphere in a pipette and (4) monitoring with better than 10-nm precision the position of the capsid-distal sphere during DNA packaging (Fig. 3a). This type of measurement is sometimes called *nanometry*.

As the DNA molecule is packaged, the capsid-distal latex sphere moves in the optical trap (Fig. 3b). As the capsid-distal latex sphere moves, the optically derived force on the sphere increases until the packaging is completely stalled.

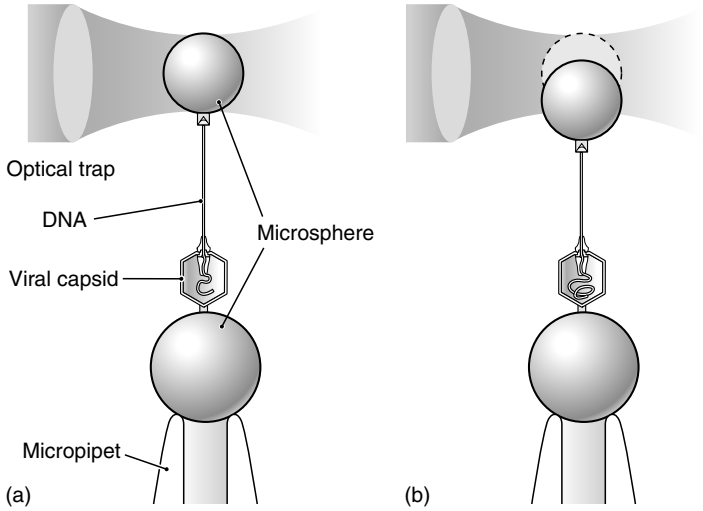

Fig. 3 Nanometry of a DNA molecule while it is being packaged in a bacteriophage capsid. (a) The DNA packaging motor after the DNA molecule begins to enter the capsid during nanometry. (b) The same DNA packaging motor after further DNA entry in the conditions of nanometry.

The relationship of force to packaging rate is measured. The stall force for bacteriophage ϕ29 DNA packaging motors varies between 40 and 70 pN. This stall force is larger than the stall forces for RNA polymerase and various eukaryotic motors that have been (partially) reconstructed *in vitro*. To obtain the force present throughout packaging, the packaging is allowed to proceed by feedback regulating the position of the pipet in Fig. 3 so that the optical trap exerts constant force. As DNA enters the capsid, the packaging rate is used to measure the force being used to raise the potential energy of the packaged portion of the DNA molecule. That is to say, this measurement supplies the force needed to calculate the energy of DNA compaction. This energy was 0.56 kcal mol^{-1} of nucleotide pair, in agreement with both the theory and the experiment described above.

The above agreement on the energy of compaction was found among three totally different strategies. This type of agreement is difficult to achieve unless all three strategies are basically producing accurate results. This conclusion is especially important for the nanometry because nanometry is a comparatively new discipline with not all potential sources of distortion well understood. Effects of the high density of surfaces are potentially important. But, the above data indicate that this does not change the measurements. In any case, the inside of a cell is very surface intense. So, perturbation by surfaces, if found, is not necessarily to be regarded to be an unproductive distortion (artifact).

2.2 DNA Packaging Motors

By analogy with the information needed to understand macroscopic motors (internal combustion engine, for example), the information needed to understand DNA packaging motors is the following: (1) a complete list of relevant variables that describe the motor's state (position of valves, current in spark plugs, and so on, in the case of an internal combustion engine) and (2) a description of how each of these variables changes as a function of time. In the case of a biological motor, one faces the following major problem: One normally works with an ensemble of motors. The ensemble is difficult, if not impossible, to synchronize. In any case, the motors are small enough so that thermal motion causes any synchrony to be lost.

One solution to the synchrony problem is to measure the time-dependence of state variables of a single motor. For example, the nanometry of the previous section has also yielded a plot of length of DNA packaged as a function of time. That is a beginning, but only a beginning because only one state variable (length of DNA packaged) is measured. Nonetheless, the nanometry yields the interesting observation that the rate of DNA packaging has the following two deviations from constancy as a function of time: (1) The rate smoothed for small fluctuations progressively decreases as a function of time. (2) The rate has a repeated small fluctuation that consists of a pause. That is, the rate sometimes becomes zero. The frequency of pauses increases dramatically as more DNA is packaged.

The first observation raises the question of whether the rate also undergoes a time-dependent decrease inside of an infected cell (*in vivo*) or, perhaps, in an *in vitro* system that accurately mimics the *in vivo* system. After all, the biology of survival leads to the conclusion that, if anything, the rate should increase once the DNA packaging motor has committed

to packaging a genome. Proposing an increase in the rate is equivalent to proposing feedback control for the DNA packaging motor, on the basis of the energetics discussed above. Complexity introduced by feedback control is the key differentiating factor between a process that is called *physical* and a process that is called *biological*. In the case of the motors of higher organisms (the motor that moves muscle, for example), the question of feedback control cannot be asked with current *in vitro* systems because these systems have been stripped of most of the components that they have *in vivo*. In the case of DNA packaging motors, this question has not yet been answered.

The observation of pauses raises the question of whether the pauses are part of the function of the motor or, alternatively, a trivial product of overcoming the resistance to packaging. The answer to this question is also not known. To further investigate the DNA packaging motor, more state variables must be measured in real time at the single-motor level while the motor is running. The best strategy appears to be the use of single-motor fluorescence microscopy, perhaps in conjunction with the nanometry of Fig. 3. Fluorescence microscopy has the capacity to observe either a single DNA molecule or its capsid (or both) during packaging. Importantly, fluorescence microscopy has the capacity, in theory, to measure several state variables simultaneously.

3
In vitro DNA Packaging: Complex System Biochemistry

The importance of the fidelity of *in vitro* systems is illustrated by examples from studies of the initiation of DNA packaging. Initiation of DNA packaging has not been discussed above because of its complexity and variability among bacteriophages. The first example is the finding that *in vivo* initiation requires transcription in the case of the related bacteriophages, T3 and T7. However, a purified T3 *in vitro* system has absolutely no dependence on transcription! Nonetheless, a much less purified *in vitro* system was developed and this latter system did have dependence on transcription. The added complexity of transcription presumably occurs as an adaptation to improve packaging success through control of packaging.

A second example is the finding in a very unpurified *in vitro* system that bacteriophage T7 DNA packaging initiation is cooperative among several capsids. This observation is not totally surprising because the capsids are packaging genomes that are all on a single DNA concatemer. However, purified *in vitro* systems have lost their specificity for concatemers and, therefore, would not have revealed the cooperativity. The use of an unpurified *in vitro* system, therefore, has some major advantages. Furthermore, the unpurified *in vitro* T7 system has the technical advantages that in this system (1) fluorescence microscopy can be used to observe both single DNA molecules and single bacteriophage capsids and (2) the system either reduces or eliminates photobleaching; photobleaching is potentially a major problem.

The point is well made in this case that the long-range interest of understanding biology does not coincide with the short-range interest of having neat *in vitro* systems. The long-term eventually arrives, though sometimes suddenly and after a long period of wondering where it is. Progress is not necessarily colinear with time.

double-stranded form. Any of these four possible molecules can serve as a virus genome.

Virus Genome Packaging
The event in which the viral nucleic acid is placed inside the protective viral coat.

Viruses are obligate intracellular parasites composed of virus-specific nucleic acid and a protective coat. During virus assembly, the critical stage is the specific recognition of the viral genome with the maturing virus capsid leading to encapsidation (packaging) of the genome to the protective capsid. The formed and released viral particle is metastable, being primed to deliver the genome upon interaction with a new host cell. Viruses with an RNA genome either condense their nucleic acid concomitantly with the capsid assembly or produce empty capsids (procapsids), which translocate the viral genome into the particle in reaction requiring chemical energy in a form of NTPs. RNA viruses can have one to twelve genome segments. It is obvious that very delegate mechanisms have evolved to assure specific packaging of the entire genome either to a single or several particles.

1 Background

Viruses are intracellular parasites that are fully dependent on the metabolic apparatus of the cell. The viral genome has the information for its multiplication in the cell as well as for directing the synthesis of structural components of the virion. The virus genome can be either DNA or RNA, double-stranded (ds) or single-stranded (ss). The nucleic acid interacts with the viral structural proteins to form a nucleic acid–protein complex. This event is referred to as *nucleic acid packaging or encapsidation*, and the formed protein coat protecting the nucleic acid is the *virus capsid*. The capsid can be organized either helically or icosahedrally. In the helical nucleocapsid, an elongated rod-shaped structure, the coat proteins form a helix around the genome. The icosahedral capsid is a spherical shell-like structure enclosing the condensed viral genome (Fig. 1). In some viruses, a membrane additionally surrounds these structures, or is located underneath the capsid.

Double-stranded nucleic acids are antiparallel molecules. In the case of RNA, the strand that can serve as the messenger in protein synthesis is known as the (+) strand and the complementary strand as the (−) strand. There are RNA viruses that have either (+), (−), or dsRNA as their genome. The genome can be a single RNA molecule or segmented. The genome segments can reside in a single capsid or in different capsids (multipartite). The (+)-strand RNA genomes, upon introduction to the cell, can serve directly as messengers, whereas the (−) strand and dsRNA genomes must be transcribed to (+) strands in the cell. This (+) strand synthesis is carried out by virion-associated polymerases, either directly or via a DNA intermediate (retroviruses).

One of the key events during virion assembly is the encapsidation (packaging) of

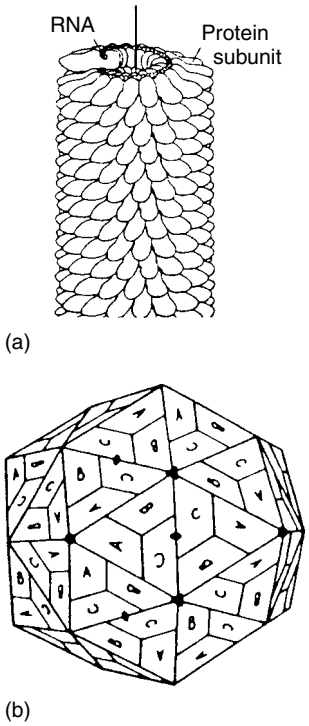

Fig. 1 Principal structural arrangements of virus capsids: (a) A helical capsid, with the coat proteins organized helically around the viral RNA (e.g. tobacco mosaic virus), (b) An icosahedral capsid in which the coat proteins (A, B, C) form a spherical structure enclosing a condensed viral RNA molecule (e.g. a plant (+)-strand RNA virus).

the viral genome into a protein capsid. On the basis of the great variety of genome strategies in RNA viruses, there evidently must also exist variations in the mechanisms used for RNA packaging. It is obvious that only very specific interactions between the RNA and the capsid protein(s) can produce the distinct detection of the viral RNA molecules in the cell and their subsequent packaging. The formation of a functionally metastable virion structure, owing to its responses to stimuli during the virus entry, results in virion disassembly and genome activation. Our understanding of the RNA packaging events relies mostly on a few model systems, but information from a great variety of viruses is rapidly accumulating. This article describes various examples of RNA virus systems about which more detailed packaging information is available.

2 Tobacco Mosaic Virus (TMV), the Classic Case

Tobacco Mosaic Virus (TMV) is a rod-shaped virus composed of a (+)-sense ssRNA molecule (6395 nucleotides) associated with some 2130 identical capsid protein molecules forming a helical structure (Fig. 1a). As long ago as 1955, an *in vitro* reconstitution of infectious virus particles from purified RNA and dissociated coat proteins was achieved. This self-assembly reaction of purified components allowed a detailed study of the packaging mechanism.

The nucleation of the TMV particle starts from the interaction between the genomic RNA and the coat-protein aggregate (the so-called 20S particle or *disk*). The disk is a two-layer cylindrical structure, each layer composed of a ring of 17 coat-protein molecules. An internal region of the RNA called the *origin of assembly* (OAS), located in the region between nucleotides 5443 and 5518, forms a bulged stem-loop structure that binds round the first turn of the disk. This leads to the melting of the base-paired stem and causes the disk to dislocate into a short helix (the ''lock-washer'' form) entrapping the RNA. The helix elongation continues towards both directions of the RNA molecule. The 5′ direction encapsidation is rapid, whereas

the 3′ direction encapsidation is slow. Furthermore in the 5′ directed reaction, RNA passes through the lumen of the growing rod as it is incorporated into the virion, and predominantly uses the disk subassembly of protein subunits as building blocks. The 3′ direction reaction uses smaller aggregates or single protein subunits. The assembly process is greatly dependent on the pH and ionic conditions, as is the disassembly upon infection. The genome length determines the length of the virion.

3 Small, Icosahedral, Positive-strand RNA Viruses

Small (+)-strand RNA viruses have been found infecting bacteria, plants, and animals. These viruses are among the simplest replication systems. High-resolution structural data, which are available for a number of such viruses, have greatly advanced our understanding of the assembly of these small viruses. The overall structural principles are surprisingly similar in ssRNA viruses infecting plants and animals (Fig. 1b), whereas a different arrangement is found in the corresponding bacterial viruses. In spite of the structural similarities of the capsids, the condensed RNA molecule inside the capsid can be organized differently. It can be either randomly organized (so that it does not contribute significantly to the diffraction pattern obtained from virus crystals) or parts of the RNA can be associated with the capsid proteins in a symmetric fashion (making part of the nucleic acid visible in the X-ray-derived electron density map).

Bacteriophage assembly initiation of ssRNA is probably the best understood among small, icosahedral (+)-strand viruses. These viruses (MS2, R17, etc.) have one coat protein that exists as a dimer. Initially, coat proteins bind specifically to an asymmetric RNA hairpin loop 21-nucleotides long (Fig. 2), which is located in the translation initiation region of the replicase gene. All unpaired nucleotides are necessary. There are two A residues in the loop that are base-specific. There is also an unpaired A in the stem which cannot be changed without loss of activity. The paired stem nucleotides, however, do not show any base specificity (compare also to yeast virus L-A packaging signal in Sect. 4.2: Fig. 5). Later in the infection, when the coat-protein concentration in the cell increases, the binding of the coat protein to this RNA loop leads to translational repression of the replicase synthesis and is most probably also responsible for the initiation of the genome packaging. The initial

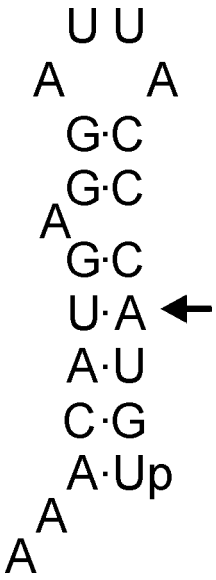

Fig. 2 The bacteriophage R17 coat protein–binding site just upstream of the replicase gene in the R17 genome; the arrow indicates the starting point of the replicase gene.

binding stimulates the binding of additional coat-protein dimers to nonspecific sequences, resulting in a highly cooperative assembly of coat proteins, forming a shell that simultaneously encloses the viral RNA.

An intact ssRNA bacteriophage capsid also contains a single copy of a maturase protein, which is necessary for infection. It has been shown to bind RNA, but capsid proteins can specifically package virus-specific RNA without this protein. In the model represented by ssRNA bacteriophages, the RNA genome is condensed to the capsid simultaneously with the protein shell assembly. Both picornaviruses as well as certain plant viruses (e.g. southern bean mosaic virus, tomato bushy stunt virus, turnip crinkle virus) assemble via discrete intermediate units.

In the turnip crinkle virus assembly model, three coat-protein dimers bind to a specific viral RNA sequence. The N-termini of these proteins are located around the threefold symmetry axis. Additional dimers are then added to this structure. A preformed capsid-packaging model is not yet, however, completely ruled out. Anyway, the packaging is very specific for the (+)-sense genomic RNA. The packaging signal is a 28 nt bulged hairpin loop in the 3′ end of the coat protein coding region, and the size of the packaged RNA is critical for stable assembly of the virions. The picornavirus genomes also contain a 5'-terminal covalently linked protein, but it is not the specificity factor for packaging.

Ordered ssRNA has been observed in the crystal structure of bean pod mottle virus, a comovirus. Some 20% of the RNA is icosahedrally oriented with no sequence specificity. Whether this RNA–capsid protein interaction has implications for RNA packaging remains to be seen. These viruses, however, can form stable empty capsids, indicating that correct capsid protein–protein interactions take place without the genomic RNA. On the other hand, a nodavirus (flock house virus) capsid has been shown to bind portions of the genomic ssRNA in a dsRNA form. About 10 bases in the dsRNA form bind to the coat proteins at the icosahedral twofold axes. The dsRNA is in the A form and is formed from the secondary structures of nonunique sequences. This RNA is an integral part of the capsid quaternary structure, thereby suggesting capsid condensation around the RNA. This model is also supported by the absence of reports of empty precursor particles in nodavirus-infected cells.

4
Double-stranded RNA Viruses

Since cellular polymerases are not capable of operating on dsRNA templates, all dsRNA viruses have a virion-associated, RNA-dependent RNA polymerase. Although in many cases dsRNA viruses have segmented genomes, many fungal viruses have only a single genome segment. The viruses with segmented genomes, in addition to having the specificity for selecting viral RNA for packaging, must have a mechanism ensuring that one copy of each genome segment is included in the virion. Depending on the virus, the number of segments can vary from 1 to 12. Here we concentrate on two dsRNA virus systems (ϕ6 and L-A), where *in vitro* assembly experiments have shed light on the RNA encapsidation reaction.

4.1
Bacteriophage ϕ6

Pseudomonas syringae virus ϕ6 is the type organism of the *Cystoviridae* family

of dsRNA bacteriophages. Like other members of the family, it has three genomic segments that are named according to their sizes (large, L, 6374 bp; medium, M, 4063 bp; and small, S, 2948 bp). These are packaged into a dodecahedral polymerase complex particle made of four viral proteins, which are encoded by the genome segment L. Protein P1 is the major component of the capsid, and forms the structural framework for the particle. It is responsible for the initial binding and recognition of the genomic (+)-strand ssRNAs. P2 is an RNA-dependent RNA polymerase and resides inside the particle at -fivefold symmetry positions. P4 is a nonspecific NTPase forming hexameric, ring-like structures that are located at the particle surface around the fivefold symmetry axes. It provides the energy for the genome packaging and acts also as a helicase. P7 is a small particle stabilizing protein and is needed for stable ssRNA packaging. An additional layer of protein P8 surrounds the polymerase complex particle, forming the nucleocapsid (NC). The nucleocapsid resides in a virus-specific membrane envelope.

Packaging of ϕ6 ssRNA has been studied by using an *in vitro* packaging assay. Empty polymerase complex particles (PCs) can be produced in *Escherichia coli* cells from a plasmid containing a cDNA copy of the L-segment. Purified particles can package, replicate and transcribe the viral RNA segments. The purified NC shell protein P8 can be assembled onto the dsRNA-filled particles, thus making them infectious to spheroplasts of *P. syringae* and leading to the production of infectious complete viruses.

The virus enters the cell via membrane fusion and endocytosis-type events, and loses the structural layers sequentially. In the cytoplasm, NC is activated by the removal of the protein P8 layer. This activation leads to the production of (+)-strand transcripts from all genomic segments (l^+, m^+, and s^+). The L-segment-encoded polymerase complex proteins are synthesized early in infection and self-assemble to empty dodecahedral particles. The synthesized (+)-strands serve also as precursor genomic strands, which are packaged to these polymerase complex particles. The packaging is specific for ϕ6 RNA and the packaging sites determine this specificity. These packaging signals extend for some 210 to 280 noncoding nucleotides from the 5′ end of each segment (Fig. 3). The 18 first 5′ nucleotides are conserved in all segments. In each segment, there is also a 10–12-nucleotide-long homologous sequence within the first 100 nucleotides from the terminus. This sequence forms a hairpin structure with a very stable tetraloop UACG. This is thought to be a ϕ6–specific signal in the packaging sites. In segment s^+, there is an extra copy of this tetraloop. Otherwise, the secondary structures of the packaging sites are very different, although some similar single-stranded regions between s^+ and m^+, and m^+ and l^+ segments can be observed.

Packaging of ϕ6 RNA is sequential. The polymerase complex recognizes the three ssRNA genomic precursor molecules in a segment-specific manner and translocates the RNA molecules into the interior of the particle so that the s^+ segment is packaged first, followed by m^+ and then l^+. The next step in the virus life cycle is the synthesis of the (−)-strands, which occurs inside the polymerase complex particle using the (+)-strands as the templates. The (−)-strand synthesis is coupled to the packaging in such a way that it does not occur before the packaging of l^+ segment has started. The particles with

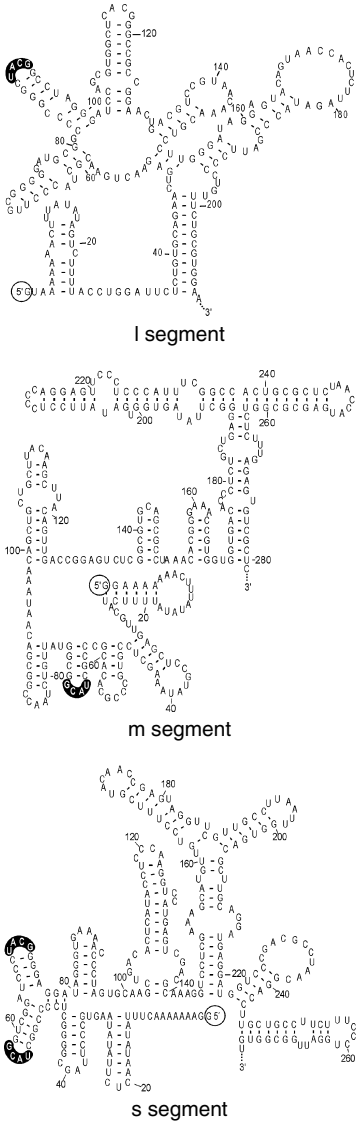

Fig. 3 Secondary structures of the packaging regions of bacteriophage ϕ6 (+)-strand genomic segments based on chemical and enzymatic probing and phylogenetic comparisons. Conserved secondary structure elements are highlighted in black.

synthesized dsRNA genomes move to (+)-strand synthesis mode.

The polymerase complex particle has to go through considerable conformational changes during packaging and particle maturation. The empty particle is smaller and more angular than the dsRNA-filled particle. Estimations of the inside volumes of different particles show that the particle has to expand during ssRNA packaging in order to have enough space for all the three segments. This could explain the sequential packaging: different segment-specific high-affinity binding sites are exposed on the particle surface upon particle expansion.

Energy for the packaging is provided by the NTP hydrolysis carried out by the P4 hexamers. One of these hexamers, however, is chemically distinct, being attached to the particle in a more stable manner. Mutant or detergent-treated particles containing reduced amounts of P4 (equivalent to occupancy of one vertex only) have shown to be efficient in RNA packaging and (−)-strand synthesis, but the (+)-strand synthesis in these particles is completely abolished. It can be concluded that the P4 hexamers are needed both in RNA packaging and (+)-strand synthesis, and the vertex used for packaging cannot be used in (+)-strand synthesis (mRNA exit).

Figure 4 depicts the NC activation, procapsid packaging, and NC maturation. It remains to be seen whether members of the reovirus family follow this general scheme for their RNA packaging. It is intriguing to address the specific RNA–protein interactions leading to the highly selective packaging of all the viral genomic RNA segments.

4.2 Yeast Virus L-A

Yeast dsRNA virus L-A is a degenerate virus, as are all viruses residing in fungi.

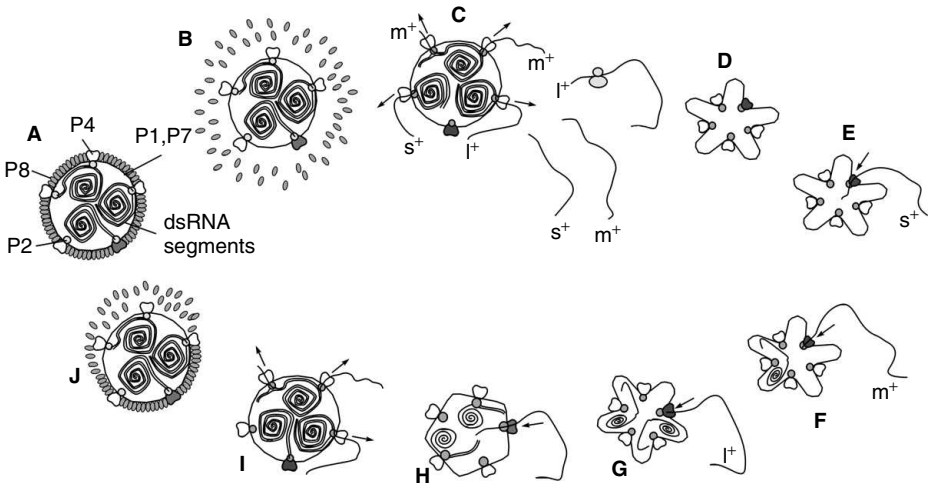

Fig. 4 Bacteriophage ϕ6 packaging and replication model. (a) Protein and RNA components of the nucleocapsid, (b) nucleocapsid activation by the removal of P8 shell, (c) transcription of (+)-strand genome segments, (d) assembly of empty polymerase complexes coded by the large genome segment, (e–g) sequential packaging of the genome segments through the packaging vertex, (h) initiation of (-)-strand synthesis, (i) (+)-strand synthesis, and (j) inhibition of (+)-strand synthesis by the assembly of P8 shell.

They exist intracellularly only, and no external virus particles have been observed. L-A is a parasite of *Saccharomyces cerevisiae*. The L-A system also supports the replication of several satellite dsRNAs in addition the viral genome. The L-A genome is a 4.6-kb long, single dsRNA molecule, whereas all the satellite dsRNAs are smaller. The satellites code for a secreted toxic protein and for immunity to that toxin.

The L-A genome codes for the major capsid protein (Gag) and for a fusion protein that has a Gag as its N-terminal and an RNA polymerase domain as its C-terminal portion (Gag–Pol). The Gag-Pol fusion protein is formed by a −1 ribosomal frameshift event. The frameshifting efficiency controls the formation of the Gag–Pol protein. *In vitro*, ~1.8% of the Gag transcripts are read to produce Gag–Pol fusion protein. The ratio of Gag to Gag–Pol production is very close to that estimated from the isolated virus particles; 120 Gag proteins, 2 Gag–Pol proteins (and one RNA molecule).

At about 400 nucleotides from the 3′ end of the (+)-strand, there resides a 24-base stem-loop structure with a five-nucleotide stem and an A bulged at the 5′ side of the stem. This structure and ten 5′ adjacent bases form the RNA packaging site (Fig. 5). The RNA packaging site binds to the Pol domain of the Gag–Pol fusion protein. The stem structure, but not the sequence of the stem, is necessary for the binding. The loop sequence, as well as the bulged A residue, however, are critical for the binding.

The packaging model involves the formation of an initiation complex where two Gag–Pol proteins dimerize and bind one (+)-strand RNA molecule. The Gag domain of the fusion protein primes the assembly of additional Gag proteins to form an icosahedral shell, condensing the RNA inside (Fig. 6). The possibility of packaging

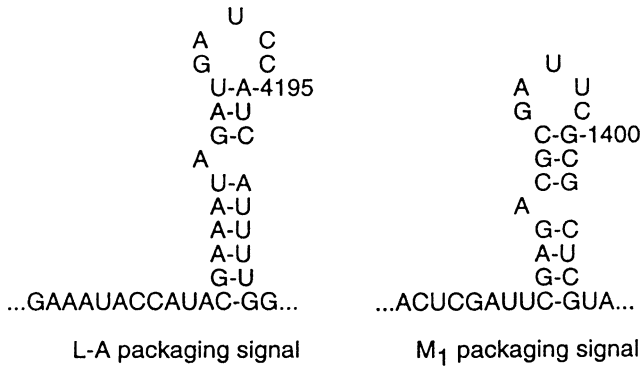

Fig. 5 Packaging signal of the L-A virus and that of its satellite RNA M_1. The structures are very similar and the loop sequences nearly identical. (Figure kindly provided by Dr. Reed B. Wickner, U.S. National Institutes of Health.)

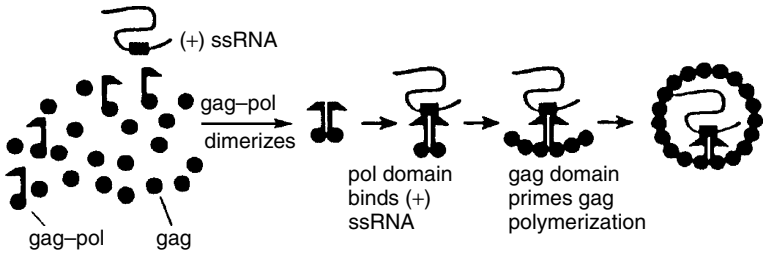

Fig. 6 RNA-packaging model of the L-A family of dsRNA viruses. (Figure kindly provided by Dr. Reed B. Wickner, U.S. National Institutes of Health.)

of a preformed capsid is, however, not completely ruled out.

Following packaging, the (−)-strand synthesis takes place inside the particle. The particle size is designed to give room for a single L-A dsRNA genome. If, however, the particle packages a short satellite RNA using a mechanism and a mode of signaling similar to those for the L-A genome, the RNA synthesis produces progeny RNA molecules that stay inside the particle as long as the RNA mass is equal to that of the L-A genome. This system results in particles with multiple dsRNA segments, the number depending on the size of the packaged molecule.

5
RNA Packaging Signaling in Animal Viruses

5.1
Sindbis Virus

Sindbis virus, a togavirus, has icosahedral symmetry. The assembly of the virion requires two steps. First, the genomic (+)-strand ssRNA interacts with the capsid protein leading to the formation of the nucleocapsid. Second, the nucleocapsid specifically interacts with the viral membrane proteins, which are translocated to the plasma membrane. This event results in the release (budding) of viruses. The genomic RNA is used to translate the nonstructural proteins from the 5′ portion

of the molecule. Structural proteins are translated from a subgenomic RNA (identical to one-third of the 3′ end of the genomic RNA). Only the genomic RNA, and not the subgenomic fragment, is packaged. The packaging signal is located at a 132-nucleotide region (between nucleotides 945 and 1076 in the Sindbis virus genome).

The binding site with predicted strong secondary structure lies within the coding region of a nonstructural protein nsP1. The binding of this region to the capsid protein is supposed to trigger protein–protein interactions between the capsid proteins leading to the nucleocapsid formation. The crystal structure of the Sindbis virus capsid protein reveals a dimer. However, monomeric capsid protein binds RNA. The RNA binding site is some 30-amino acids long around amino acid 100 of the protein, which is about 246-amino acids long. The binding site is located between two domains of this protein. The N-terminal domain is largely unstructured (flexible) and basic, a good candidate for an RNA interacting protein. The other domain forms the capsid structure.

5.2
Mouse Hepatitis Virus

Mouse hepatitis virus, a coronavirus, is an enveloped virus with a helical capsid. The genome is a positive-sense ssRNA molecule. Also, in this case there are subgenomic RNA species in addition to the genome-length species. Only the genome-length RNA is packaged. Deletion mapping has located the packaging signal to a 190-nucleotide internal sequence close to the 3′ end of gene 1. There are indications of a stem-loop RNA structure in this region. The nucleocapsid protein N has been shown to bind all viral mRNAs, whereas a transmembrane viral envelope protein M binds specifically to the packaging signal. This is the first known example of an RNA virus in which interaction between a viral envelope protein and RNA packaging signal determines the selective RNA packaging into viral particles.

5.3
Influenza Virus

The influenza virus, an orthomyxovirus, has eight different ssRNA genome segments of negative polarity, which are associated with four polypeptides forming a ribonucleoprotein core. This core exhibits RNA-dependent RNA polymerase activity and is enclosed into the viral envelope. Of the terminal untranslated 3′ and 5′ nucleotides of the genomic RNAs, about 15 are involved in forming a circle via a panhandle structure. Some 20 nucleotides at the termini of the segments are sufficient signals for transcription, replication, and packaging of the RNAs into the virus particles. It is assumed that the packaging of the genomic segments is not accurate, but more than eight segments are packaged. This somewhat random packaging leads to different assortments of genomic segments among the viral particles. Thus, with only a few particles having complete sets of genomic segments, specific infectivity should be low, as in fact has been observed. However, a more specific packaging system has not been ruled out.

5.4
Hepadnaviruses

In both the hepadna- and retroviruses, the packaged nucleic acid is positive-sense RNA, but the virus particle contains an RNA-dependent DNA polymerase (reverse

transcriptase), which converts the packaged RNA to DNA form.

Hepadnaviruses are small, enveloped icosahedral particles. Upon infection, the nucleocapsid is transported to the host cell nucleus. The 3.2-kb genome is converted into a covalently closed circular molecule, which is transcribed to a genome-Iength RNA molecule, as well as to two subgenomic RNAs. Only the genome-length (+)-strand RNA is encapsidated to the nucleocapsid along with the reverse transcriptase. At this stage, the packaged RNA molecule acts as a template for the synthesis of the complementary (−)-DNA strand, which is further synthesized to a partially duplex DNA molecule. The nucleocapsid acquires the virus-specific envelope from the endoplasmic reticulum, after which the viral particle is removed from the cell by the vesicular transport pathway.

The genome-length RNA in the hepadnavirus contains a region designated as "ε". It is a sequence about 90-nucleotides long, located near the 5′ end of the molecule, and it is necessary and sufficient for genome packaging. The same signal is also found at the 3′ end of the genome but does not have packaging activity at this position. The ε sequence forms a hairpin loop, which also binds the reverse transcriptase and is the initiation site for the reverse transcription. Even though the packaging is coupled to reverse transcription, these two events are independent. Nonfunctional reverse transcriptase does not prevent packaging. However, if there are no reverse transcriptase proteins available, only empty capsids are formed. The capsid (core) protein has a basic C-terminus that might have nonspecific nucleic acid binding functions. It is not, however, clear how ε, reverse transcriptase, and the capsid proteins interact to initiate the encapsidation reaction. An interesting feature in hepadnavirus packaging is a cis preference. When wild-type genomes are used to complement reverse transcriptase mutants, the progeny genomes packaged are preferentially of wild-type origin.

5.5 Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) is an enveloped polyhedral retrovirus with a (+)-strand 9.2 kb RNA genome. As in other retroviruses, the viral particle contains two copies of the genomic RNA molecule. Upon entry into the host cell, the retroviral RNA genome is converted into a DNA molecule by the virion-associated reverse transcriptase. After the virus particle has entered the nucleus, the viral genome integrates with the host genome. The integrated provirus is transcribed by the cellular RNA polymerase II, producing full-length genome transcripts. These are spliced to subgenomic RNAs encoding viral regulatory proteins including Rev. Later in the infection, the accumulation of Rev and its binding to the Rev-responsive element (RRE) located at the 3′ end of the Env gene stabilizes these RNAs and splicing is avoided or limited. Rev contains a leucine-rich nuclear export signal, and together with cellular and possibly viral chaperone proteins the unspliced viral RNA genomes are exported from the nucleus to the cytoplasm.

Retroviral genomes code for polyprotein precursors (Gag, Pol, and Env). The virus capsid obtains the envelope by budding through the plasma membrane. The reverse transcriptase (Pol) is synthesized as a Gag–Pol fusion protein by a ribosomal frame shifting (see also Sect. 4.2 on yeast virus L-A). The Gag region produces the virion capsid proteins. After virus

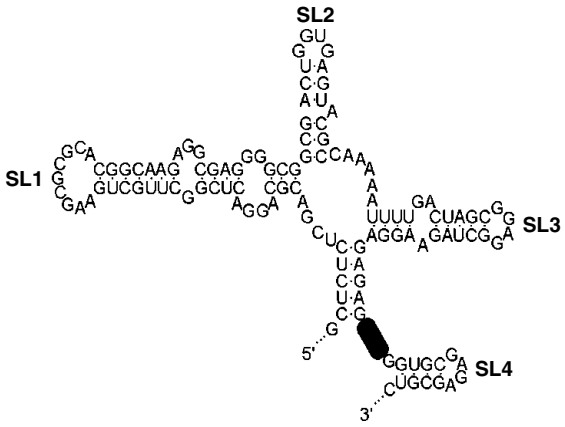

Fig. 7 Secondary structure model of the major packaging signal in human immunodeficiency virus 1. Stem loop 1 (SL1), putative dimerization initiation site. SL2, major splice donor. SL3, principal packaging determinant. Gag-initiation codon shown with gray background.

maturation, the reverse transcriptase is activated by a proteolytic cleavage, which leads to the binding of the reverse transcriptase to the RNA. It is assumed that the packaging of the reverse transcriptase is based on the Gag (capsid) domain of the fusion protein.

The packaging of retroviral RNA is highly specific, since only full-length RNAs are packaged. As in hepadnaviruses, the retrovirus RNA contains a packaging signal (ψ) near the 5′ end of the genomic RNA. Figure 7 shows the secondary structure model of this packaging region in HIV-1. Stem loop 3 contains the major packaging signal motif with the GGAG-terminal loop. This sequence has been shown to bind the zinc finger motif of the nucleocapsid (NC) region of the Gag polyprotein. Deletions in the NC zinc fingers will disrupt packaging; deletion of the stem loop 3 leads to only partial packaging defects, since the GGNG motif appears multiple times in lentiviral packaging regions. Stem loop 1 contains the dimer initiation site (DIS) with terminal palindromic loop (GCGCGC), which is able to interact with the sister genomic RNA. Stem loop 2 contains the splice donor site and has relatively little effect on packaging. There are also accessory packaging signals outside the major packaging region.

In HIV-2, the major packaging signal is in a region 5′ to the splice donor, and the packaging region is found in all RNA species. HIV-1 can also package HIV-2 RNA, but captures both spliced and unspliced RNA with equal efficiency. HIV-2 seems to package RNA in cis, cotranslationally, compensating for the presence of the packaging site in all RNA species, whereas HIV-1 is capable of picking up RNA in trans.

The hepadna- and retrovirus genomes with the RNA packaging sites indicated are depicted in Fig. 8.

6 Perspectives

Virus RNA packaging is a highly selective event, in which almost exclusively viral RNA is encapsidated. The selectivity is obtained by means of specific RNA–capsid protein interactions. These interactions may also have translational regulatory effects. There is a vast amount of information about DNA–protein interactions, but our understanding of RNA–protein

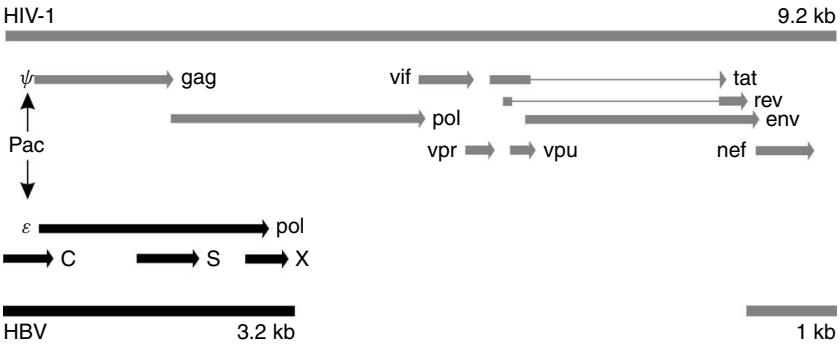

Fig. 8 Genome organizations of human immunodeficiency virus 1 (HIV-1) and human hepatitis B virus (HBV). The "Pac arrow" indicates localization of the encapsidation signals.

interactions is still relatively limited. Surely RNA viruses will be in the forefront in helping us to elucidate the interactions between the two most active cellular components, RNA and protein.

The development of recombinant DNA technologies (including reverse transcription) and the understanding of the packaging signaling in many virus systems have opened the opportunity to package not only the viral RNA but also heterologous RNA into viruses. These advances are of crucial importance in helping us to understand the packaging mechanisms.

It is presumed that RNA viruses will play an important role in the fast-developing field of RNA biology, including gene silencing. The ability to package and amplify desired RNA segments, either single- or double-stranded, is an asset that will certainly be utilized.

DNA Repair
Enzymatic processes that survey and repair damage to DNA.

Nucleotide Excision Repair
DNA repair process that removes bulky DNA base lesions.

Abbreviations

NER	nucleotide excision repair
BER	base excision repair
MMR	mismatch repair
UV	ultraviolet
8-oxoG	8-hydroxyguanine
Adduct	DNA damage, chemical association with a DNA base
Lesion	DNA damage
Glycosylase	enzyme that cleaves the glycosylic bond between the DNA base and the sugar-phosphate backbone of DNA
ROS	reactive oxygen species
pol β	DNA polymerase β
CS	Cockaynes syndrome
WS	Werner syndrome
TCR	transcription coupled repair
GGR	general genome repair
mtDNA	mitochondrial DNA

All living organisms are constantly exposed to exterior agents and endogenous sources that interact with the macromolecules and cause substantive damage. This damage affects the function of all cellular macromolecules, including proteins, RNA, and DNA, and the damage accumulates over the life span of individuals. While RNA and proteins can be resynthesized, the genetic material, DNA, is the master molecule of life and it needs to be maintained intact for normal cellular functions to take place and to avoid death and disease. Thus, cellular steps have evolved to remove this damage from DNA. These processes are called DNA repair, and they involve a series of enzymatic processes that detect the damage and remove it. There are a number of DNA repair pathways and there are molecular interactions between them, and the DNA repair processes in general also connect with a number of other cellular processes. In this chapter, I will discuss the nature of the damage to the DNA and the various DNA repair processes that exist in higher cells. Examples will be given where specific protein functions are discussed in more detail, and references will be

provided so that the reader can seek other sources for more detail. A lack of DNA repair capacity can lead to cancers and to a number of other specific disorders, and some of these will be discussed. In particular, there is a connection between defective DNA repair and both the incidence of cancer and the aging process.

1 Introduction

DNA is the master molecule that serves as the blueprint for the formation of all proteins and enzymes in every organism. The proteins then generate all the other substances in our cells. Thus, it is essential for reproduction, growth, maintenance, and for sustaining normal living that the DNA remains intact so that the genetic code can be read correctly. The stability and quality of the DNA is a prerequisite for normal cellular functions and there is good evidence that damage to the DNA can lead to cellular dysfunction, cancer and other diseases, cell death, and aging. A major theory holds that much of the aging phenotype (changes that can be observed) is caused by the gradual accumulation of DNA damage over a life span. DNA damage occurs at a high frequency because of metabolic processes and environmental factors such as various exposures to chemicals and radiations and the intake of food and drugs. The prevention or repair of DNA damage is thus a major concern in biology and medicine.

Cells contain an elaborate defense system against damage to DNA. There are processes that prevent the formation of the damage and there are processes that remove the DNA damage once it has formed. This latter system is called DNA repair, and it involves a multitude of specific proteins that can be subdivided into a set of different molecular pathways. These molecular processes interact with each other and also have strong interactions with other cellular processes. For example, DNA repair pathways are directly linked to the transcription machinery. The DNA is constantly scanned and surveyed, and as soon as a DNA lesion is detected, the repair enzymes are directed to it so that it can get repaired. In recent years, we have gained much new insight into these DNA repair processes and how they interact with other processes, and this has lead to new understanding about disease processes and new ideas about therapeutic intervention against major diseases.

1.1 DNA Damage

The long, thin DNA molecules contain three components: nitrogen-rich bases, sugar groups, and phosphate groups. This basic structure is shown in Fig. 1. The composition of the four types of bases adenine, guanine, cytosine, and thymidine make up the genetic code. Damage to DNA can occur to any one of its components. The bases are the most reactive components and there is far more knowledge about changes to these than about changes to the sugar or phosphate components of DNA. Also, many chemicals or carcinogens will form adducts (lesions) with new chemical groups being attached to existing DNA bases. Figure 1 shows sites where DNA damage can be inflicted in DNA.

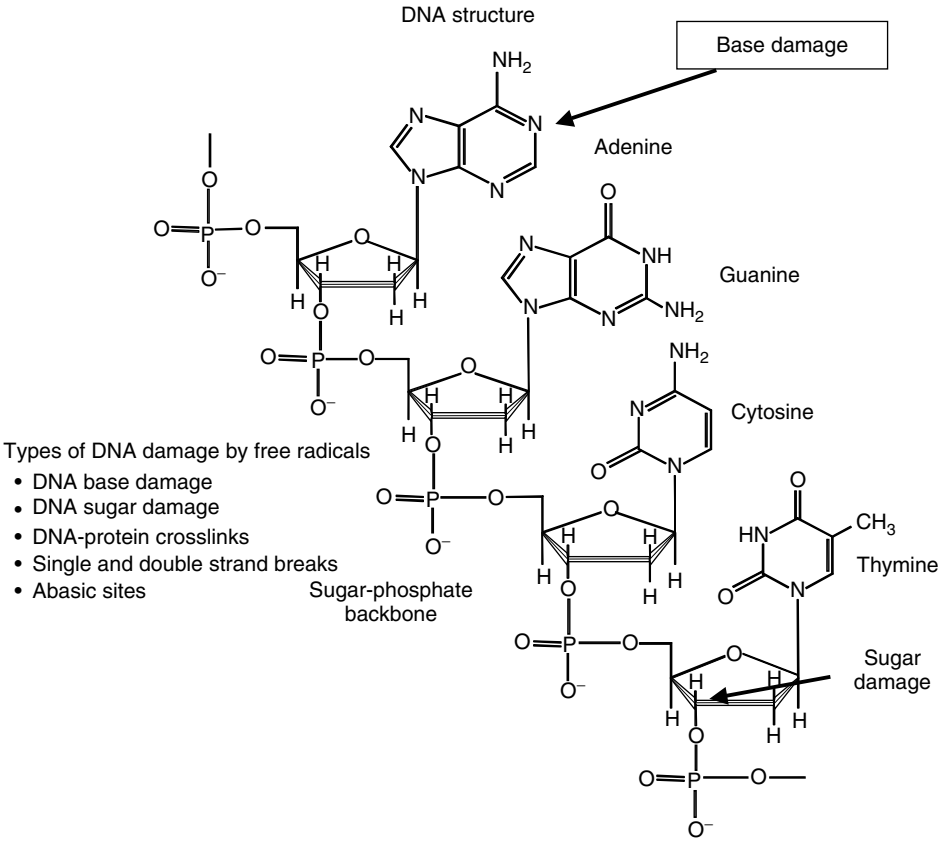

Fig. 1 Basic DNA structure and the types of damage that can be found in DNA.

1.2 DNA Base Modifications after Exogenous or Endogenous Exposures

Living organisms are constantly exposed to stress from environmental agents and from endogenous metabolic processes. For example, irradiation from various sources can directly damage bases in DNA. Ultraviolet irradiation from exposure to sunlight creates certain DNA lesions called photoproducts, shown in Fig. 2. Irradiation from γ-ray sources such as X-rays creates a large number of different kinds of lesions in DNA, including base modifications, sites with a loss of a base and breaks in the DNA strand. Since DNA contains two strands running in parallel but opposite directions, breaks can be either single stranded or double stranded. A large number of components of our food intake can directly damage the DNA. These include various carcinogens and chemicals that cause DNA damage, either by direct reactions with DNA or via metabolic modifications of the compounds that then make them reactive with DNA. For example, aromatic amines are found in variety of foods and are known to cause DNA damage and to be highly mutagenic. A number of poisons work by attacking the DNA and damaging it.

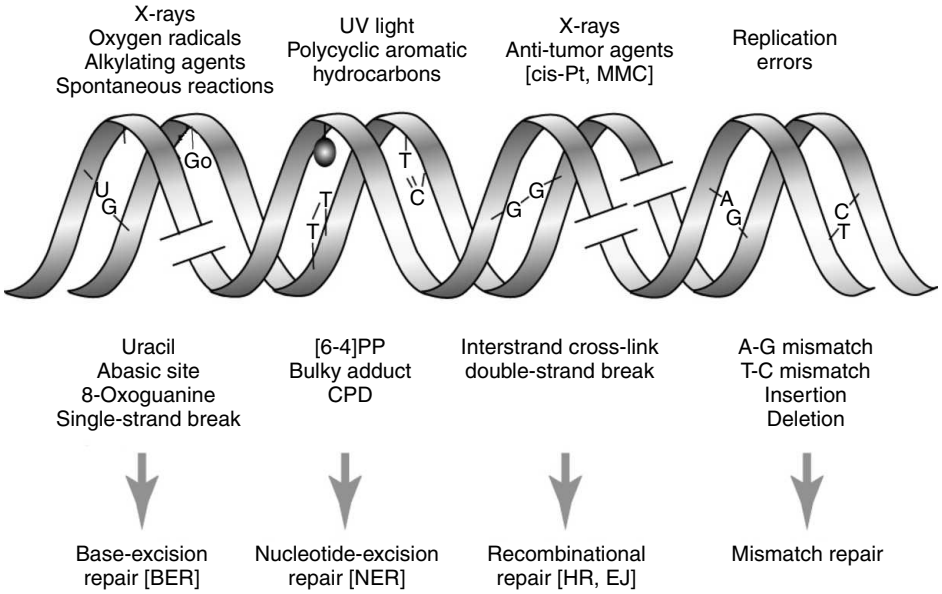

Fig. 2 Specific DNA lesions and some of the pathways that repair them.

An example of this is the poisonous gas nitrogen mustard that causes modification of DNA bases and which can also cross-link DNA bases on opposite DNA strands to generate so-called interstrand cross-links. The interstrand cross-links cause serious havoc in the cell by blocking the progression of polymerases that replicate or transcribe the DNA.

Some of the common lesions induced in the genomic DNA by different DNA damaging agents are shown in Fig. 2. This Figure also shows the various DNA repair processes that deal with the different lesions and this will be discussed later. UV irradiation generates two major types of lesions in DNA, the so-called photoproducts cyclobutane pyrimidine dimers and 6-4 photoproducts, while many DNA damaging agents induce a broad spectrum of lesions. The DNA repair pathway, nucleotide excision repair (NER), to be discussed later, removes the bulky and helix-distorting DNA adducts induced in the genomic DNA by physical and chemical agents. Chemotherapeutic agents often generate lesions varying from simple methylation of bases to complex bulky monoadducts and DNA-protein cross-links. Cisplatin is a classic therapeutic agent against cancers, and the most frequent lesion formed by this compound is the intrastrand adduct between adjacent purines (GG or AG). The major lesions induced by monofunctional alkylating agents such as methylmethanesulfonate include *N*-7-alkylguanine, O^6-alkylguanine, *N*-3-alkyladenine and O^4-alkylthymidine. Phosphotriesters can be formed by alkylation of phosphodiesters by alkylating agents. 4-Nitroquinoline 1-oxide (4-NQO) is a chemical carcinogen that forms several different types of DNA base lesions. Bleomycin, an antitumor drug, intercalates into DNA and generates free radicals resulting in single and double strand breaks, see Fig. 2. Acetylaminofluorene, a potent procarcinogen, is metabolically activated *in vivo* to form

N-hydroxy-2-acetylaminofluorene (N-OH-AAF). The aforementioned few examples illustrate the complexity of different DNA lesions that have to be dealt with to maintain the integrity of genomic DNA. Examples of some different categories of lesions are shown in Fig. 2. Some of these are more bulky than others and therefore affect the DNA structure more. Lesions can be categorized according to the degree of distortion that they afflict in the DNA, and this distortion appears to be important in the selection of the DNA repair pathway that is then chosen to remove the lesion.

Many different DNA base changes have been observed following oxidative stress, and these lesions are widely considered as instigators of the development of cancer, aging, and neurological degradation. After exposure to oxidative reagents or to oxidative stress, the resulting reactive oxygen species (ROS) attack proteins, lipids, and DNA. Since proteins and lipids are readily degraded and resynthesized, the most significant consequence of oxidative stress is thought to be the DNA modifications, which can become permanent via the formation of mutations and other types of genomic instability. The endogenous attack on DNA by ROS species generates a low steady-state level of DNA adducts that have been detected in DNA from human cells. Over 100 different oxidative base modifications in DNA have been measured in human cells, Fig. 3. The best known and most widely studied oxidative DNA base lesion is 8-hydroxyguanosine (8-oxoG), Fig. 3.

Oxidative DNA damage is thought to contribute to carcinogenesis and studies have shown that it accumulates in cancerous tissue. Notably, the cumulative risk of cancer increases dramatically with age in humans, and cancer can, in general terms, be regarded as a degenerative disease of old age. There is evidence for the accumulation of oxidative DNA damage with age, and if 8-oxoG remains in DNA, it can cause permanent alterations in the genetic code (mutations) as shown in Fig. 4. During replication, an adenine base is often mistakenly inserted into the opposite DNA strand by the DNA polymerase. In the next round of replication, the DNA polymerase now inserts a thymidine base opposite to the adenine. The result after two rounds of replication is the formation of a permanent mutation in DNA.

1.3 Detection of DNA Damage

DNA can be extracted from human cells or tissues and then analyzed chemically for its components. There are various methods to detect DNA modifications, including chemical analyses and chromatographical measurements of DNA. One issue, hotly debated, is the choice of method to purify DNA from cells or tissues. Many of the available extraction procedures introduce new DNA damage during the process of purification.

A number of enzymatic methods have been used to detect DNA damage. Here, specific enzymes or antibodies detect certain kinds of DNA base modifications and/or adducts formed in DNA. These enzymes become molecular ''probes'' for the damage and this can be a very sensitive approach. Furthermore, radioactive labeling procedures can be used as a simple and easy way to measure several modifications in DNA. In recent years, there has been a great deal of interest in detecting the oxidative DNA base modifications under various physiological conditions. Some of the methods used are shown in Fig. 5. This Figure shows some approaches for available analyses. High-pressure liquid

chromatography (HPLC) has been a useful way to detect the lesion 8-oxoG with a high level of sensitivity. More recently, mass spectrometry combined with liquid chromatography (LC/MS) has been used to detect this lesion with even higher sensitivity. Oxidative lesions other than 8-oxoG can be detected with gas chromatography or enzymatic probing, Fig. 5.

1.4 Consequences of DNA Damage

Figure 6 shows some of the cellular consequences of DNA damage. As mentioned above, DNA damage can be induced by external and internal sources. UV irradiation or ionizing irradiations are examples of exogenous sources of stress. Reactive oxygen species generated by the oxidative phosphorylation that occurs in mitochondria and thus via the cellular metabolism are examples of endogenous stress. Mutations in DNA can occur via replication of the damaged DNA whereby they become ''fixed.'' Lesion bypass or replication errors (as illustrated in Fig 4) can give rise to other forms of genomic instability, both microscopically and macroscopically. A lesion in DNA can block transcription

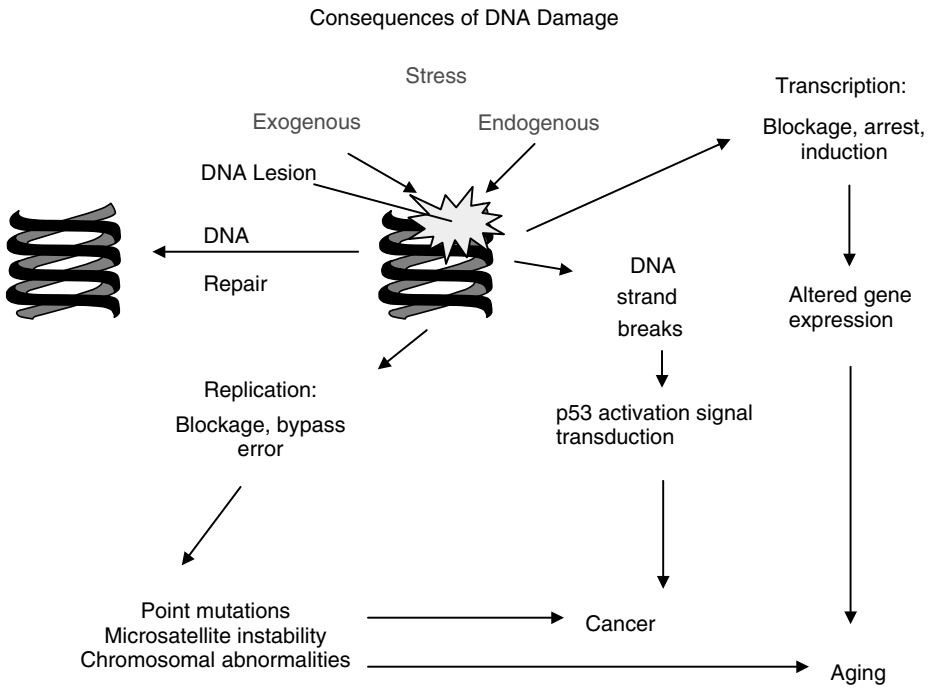

Fig. 6 Some consequences of DNA damage. Lesions in DNA can instigate a number of DNA related transactions, discussed in the text, that ultimately lead to genomic instability and other features of cancer and aging.

(conversion of DNA to RNA). It may truncate the transcript, or it may cause errors in the transcription. Alternatively, the DNA damage may induce new transcripts, and a number of genes have been shown to be inducible after various forms of cellular stress. These changes in transcription patterns that are caused by DNA damage may be part of the etiology of the malignant phenotype, as many changes in transcription have been reported in cancers. The modification of transcription caused by DNA damage may also underlie many of the changes associated with aging, where reductions, or in some cases increases, in transcriptional activity are well established. Lesions in DNA can also lead to the activation of the p53 tumor suppressor pathway leading to cell cycle arrest or apoptosis, or they can cause direct strand breaks in DNA, which again appear to be signals for several important enzymes and pathways.

It is estimated that there are several thousand DNA alterations in each cell in our organism per day caused by the endogenous and exogenous stresses, and were it not for an efficient DNA repair process, our genetic material would be destroyed by these processes over a normal human lifetime.

1.5 DNA Repair

Mammalian cells can make use of a variety of DNA repair pathways, and a schematic overview of these is listed in Fig. 7. Most studies over the years have

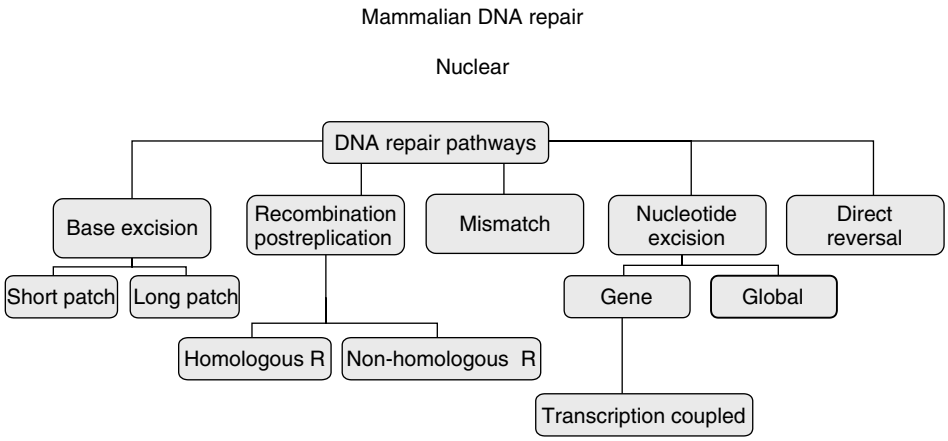

Fig. 7 Some of the major pathways of DNA repair in mammalian systems such as humans. These pathways can operate independently but are also interactive.

been based on the assumption that the DNA repair pathways listed were confined to the removal of specific lesions within certain categories. This is illustrated in Fig 2. For example, NER is the system that removes bulky lesions in DNA, such as pyrimidine dimers, cisplatin adducts, and other lesions that dramatically change the DNA structure. In contrast, base excision repair (BER) is the process responsible for the removal of simple lesions in DNA, exemplified by alkylation lesions such as methyl guanines that are considered to afflict only small structural changes in DNA and which may not represent major blocks to transcription and replication. This concept has changed somewhat in recent years as it has become evident that many of the DNA repair pathways listed in Figs. 2 and 7 are overlapping and share protein components. Thus, although it is useful to think of repair pathways as confined to the removal of different categories of DNA adducts, that distinction is becoming less certain.

It would be much too ambitious to review all the processes listed in Fig. 7. Two of the most predominant pathways are NER and BER, and these will be discussed in more detail. Mismatch repair (MMR) can protect against certain adducts in DNA and errors in DNA replication. Defects in the MMR system are closely associated with certain types of human cancers, and this pathway will also be briefly discussed. Recombinational DNA repair is a major pathway that removes certain complex lesions in DNA, for example DNA interstrand cross-links, shown in Fig. 2. This pathway of DNA repair and also direct reversal are not further described in the following. Examples of direct reversal of damage are the functions of the repair enzymes photolyase (repairs UV-induced pyrimidine dimmers) and methyl guanine methyl transferase (removes certain alkylation damage in DNA). The direct reversal processes are one-step repair that occur under certain, limited circumstances.

In general terms, the DNA repair process consists of a number of steps that act in concert to accomplish the complete repair of a DNA damage. This is shown in Fig. 8. The first step is the *recognition* of the DNA lesion, and this is carried

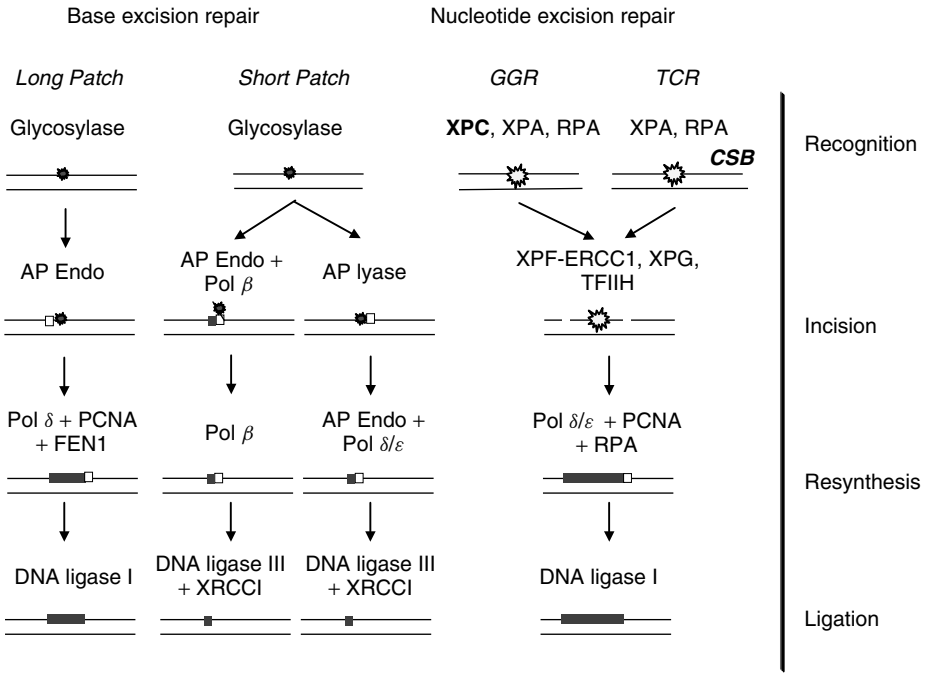

Fig. 8 The general steps in the major DNA repair pathways, and some of the proteins and steps involved in base excision repair (BER) and nucleotide excision repair (NER).

out by proteins that constantly survey the DNA for any unwanted modifications. The next step is called *incision,* and here enzymes cut into the DNA to remove the damaged DNA base. This step is complex and involves many proteins. When the damaged base has been removed, there is a step of *resynthesis,* where new DNA is generated in order to replace that which was removed in the incision step. This is accomplished by proteins called DNA polymerases, and there are several kinds of these in each mammalian cell. Since the DNA damage was in one strand of DNA, the other strand has the information required to copy itself. After the DNA synthesis, there is a *ligation* process in which the gaps in the DNA are sealed and a new intact double helix is formed.

1.1.1 Base Excision Repair (BER)

Base excision repair of oxidative DNA damage is initiated by DNA glycosylases, a class of enzymes that recognize and remove damaged bases from DNA by hydrolytic cleavage of the base-sugar bond leaving an abasic site (apurinic or apyrimidinic (AP site)). The process is shown in Fig. 8, where some of the proteins involved are indicated. Several DNA glycosylases that recognize and process oxidation products of purines and pyrimidines have been identified in human cells. The human homolog of the bacterial endonuclease III (hNTH1) glycosylase has been cloned and purified to homogeneity. Two human glycosylase genes, hOGG1 and hOGG2, have been cloned. The gene products recognize and process 8-oxoG in DNA. The glycosylases

primarily cut the glycosylic bond between the DNA base and the sugar, but many of these proteins also have an associated AP lyase activity, which then cleaves the DNA backbone and creates a nick in the DNA. There are also special enzymes, AP endonucleases, which cleave the DNA at abasic sites; the specifics of the cleavage depends upon the exact nature of the abasic site in the DNA. This results in a single-nucleotide gap that is then filled by a DNA polymerase using the intact DNA strand as a template, and the replaced gap is then sealed by DNA ligase. In mammalian cells, DNA polymerase β (pol β) is the major DNA polymerase involved in the single-nucleotide excision patch repair pathway. It was recently demonstrated that DNA pol β has an intrinsic AP lyase activity (cuts the DNA backbone like the AP endonuclease) that removes 5′-sugar-phosphate by β-elimination, and then pol β fills the single-nucleotide gap.

An alternative pathway, long patch BER, has been reported. In addition to a DNA glycosylase and AP endonuclease, this pathway involves the following proteins: flap endonuclease (FEN1), proliferating cell nuclear antigen (PCNA), DNA polymerase δ, and DNA ligase. Neither of these enzymes can remove a 5′ sugar phosphate and generate a one nucleotide gap. Instead, DNA polymerase first adds several nucleotides to the 3′ end of the nick and exposes the 5′ sugar phosphate as part of a single-stranded flap structure. This flap structure is recognized and excised by FEN1 and the DNA is finally ligated by DNA ligase. This process, shown in Fig. 8, is called long patch BER, and this type of DNA repair results in a 2 to 7 nucleotide – long newly incorporated DNA repair patch. Currently, there is much research activity in the BER area.

1.1.2 Nucleotide Excision Repair (NER)

Most of the understanding of this pathway has come through the study of the human disorder xeroderma pigmentosum (XP). There are seven genetically different types of this disease, designated A to G. XP proteins are designated according to the cell line in which they are mutated, for example, the XPA protein is the one that is mutated in XPA cells. The individuals afflicted with this condition suffer from high incidences of skin and internal cancers, hyper pigmentation, and premature aging. Cells from XP patients cannot incise their DNA at a site of a UV-induced pyrimidine dimmer photoproduct and are thus deficient in the incision process of NER. The enzymatic steps involved in NER are recognition of the lesion, incision of the DNA, excision of the damaged DNA template, resynthesis of new DNA based on the intact template, and ligation of the newly formed DNA repair patch into the reconstructed double helix. These steps and some of the proteins involved are listed in Fig. 8. The recognition step involves the XPC and XPA proteins as well as replication protein A (RPA). The incision involves the structure-specific endonucleases XPF-ERRC1 and XPG as well as the basic transcription factor TFIIH that contains the repair proteins XPD and XPB among its nine components. Interestingly, this represents a direct link between the DNA repair process and transcription since the TFIIH protein complex participates in both processes. The DNA incision process is a combination of DNA repair and transcription and illustrates the tight linkage between these processes. After incision, there is excision of the DNA strand containing the lesions, and then there is resynthesis performed by DNA polymerases followed by ligation, which

is performed by ligases. A number of recent reviews have discussed NER in much more detail.

1.1.3 Genomic Heterogeneity of NER

A major advance in the study of DNA repair has been the insight that NER and possibly other repair pathways operate with considerable heterogeneity over the mammalian genome. The NER pathway can thus be subdivided into different pathways relating to the functional and structural organization of the genome. Only about 1% of the genome is transcriptionally active, and a repair pathway entitled transcription-coupled repair (TCR) operates here. The remainder of the genome, the 99% that is inactive, has a separate pathway, general genome repair (GGR). Much work has been dedicated to the further delineation and clarification of these pathways. In the human premature aging syndrome, Cockayne syndrome (CS), TCR is deficient. CS is a rare and severe clinical condition in which the patients appear much older than their chronological age. It is a human premature aging disorder since many of the clinical signs and symptoms are those that we see in aging process in normal individuals.

1.6 Mismatch Repair

Unrepaired and misrepaired bases in DNA can arise by replication errors, spontaneous or induced base modifications, and during recombination. As for most of the other DNA repair pathways, the major understanding of this function comes from work in bacteria. Here, a process exists that recognizes the level of methylation in DNA to direct itself to the correct strand that needs repair. The proteins involved are called MutS, MutH, and MutL, and a hairpin structure is formed in DNA, which is then resolved by a DNA helicase that unwinds this structure. After that process, single-stranded DNA ends are degraded by an exonuclease, and then there is resynthesis of the DNA strand followed by ligation. Mispairings frequently transpire during DNA replication because of the limited fidelity of the DNA replicative machinery, and an incorrect base is incorporated. In human cells, a number of mismatches and aberrant DNA structures are recognized by a protein complex called MutSα, a dimer formation of the two proteins, MSH2 and MSH6. Another so-called heterodimer is the protein complex MutSβ, which also recognizes aberrant DNA structures and certain mismatches between DNA bases. The precise process as to how this pathway operates in higher organisms is not yet understood. Importantly, defects in the MMR pathway are associated with colon cancer and also with other types of cancer.

1.7 Mitochondrial DNA Repair in Mammalian Cells

Mitochondria are the energy stations inside the cells. Here, oxidative phosphorylation occurs, generating ATP. In this process, ROS are formed at high frequencies, and the mitochondrial DNA (mtDNA) is directly exposed. The mitochondrial DNA does not have a recognized chromatin structure and is thus particularly exposed to oxidative DNA base lesion formation.

There are about 1000 mitochondria per mammalian cell. Each mitochondrion has 4–5 DNA plasmids, each about 16-kb long. This means that about 2% of our total DNA is in the mitochondria. All mtDNA is transcribed whereas only about 1% of the nuclear DNA is transcribed, and thus, the mtDNA makes up a large

fraction of the total transcribed DNA in a mammalian cell.

MtDNA does not code for any DNA damage processing enzymes. It only carries the genes coding for the oxidative phosphorylation proteins and some tRNA's. Thus, all repair enzymes functioning in the mitochondria need to be transported into them. It was shown more than 20 years ago that mitochondria do not repair UV-induced pyrimidine dimers, and this observation provided the basis for the notion that there is no DNA repair capacity in mtDNA. Since then, there have been many observations indicating the presence of BER in mitochondria. BER enzymes have been identified and characterized and studies have shown that a number of simple monofunctional alkylating agents and oxidative DNA base lesions are efficiently removed from mtDNA. Other repair processes have also been detected. An important question remaining is whether mitochondria possess any capabilities to repair bulky lesions via the NER pathway.

Knowledge about mitochondrial DNA repair is limited since it has been very difficult to study this type of DNA repair. Experimental techniques and methods to study mtDNA repair have not been nearly as well developed as those for the study of nuclear DNA repair. Whereas *in vitro* DNA repair studies have been performed with great success in nuclear or whole cell extracts from cells, this kind of biochemical approach has only very recently become available for mtDNA. Recent advances suggest that mtDNA repair can now be studied using more sophisticated biochemical analysis, and this should provide great advances in the near future.

Oxidative phosphorylation in mitochondria results in the production of ROS. Several other processes contribute significantly to the pool of ROS. They include peroxisomal metabolism, enzymatic synthesis of nitric oxide, metabolism of phagocytic leukocytes, heat, ultraviolet light, various drugs such as those used in the treatment of HIV, ionizing radiation, and redox cycling compounds. Hydrogen peroxide, singlet oxygen, and hydroxyl radicals are among the ROS produced. The interactions between ROS and mtDNA result in oxidation of specific mtDNA bases. The most common oxidation products of mtDNA include 8-oxoG and thymine glycols (TG), and these base modifications have been detected in human cells. In addition, deamination of cytosine and incorporation of dUTP results in the formation of uracil in mtDNA. If unrepaired, this uracil can cause GC-AT transition mutations. Thus, insufficient mtDNA repair may result in mitochondrial dysfunction and thereby cause degenerative diseases, loss of energy formation, and pathophysiological processes leading to aging and cancer.

1.8 Age Related Changes in DNA Repair

There has been a great deal of interest in the question of whether DNA repair declines with age. Investigators have looked at many conditions of premature and normal aging and many different types of assays have been used. In general, there seems to be a growing consensus that DNA repair declines slightly with age. One study reported a 1% decline in DNA repair capacity per year with advancing age in individuals. Attempts to correlate DNA repair capacity of different organisms with maximum life span have been made. Hart and Setlow demonstrated a linear correlation between the logarithm of life span and the DNA repair capacity in

cells from different mammalian species, suggesting that higher DNA repair activity is associated with longer life span.

1.9 Diseases with Defective DNA Repair

Several human diseases are associated with defects in DNA repair. This clearly establishes DNA repair as an important function for avoiding human diseases and it suggests that therapies that enhance DNA repair may prevent disease, and thus there is great opportunity in the possibilities that lie in modulating DNA repair processes in humans. As mentioned earlier, the diseases of xeroderma pigmentosum are associated with a distinct defect in the DNA repair pathway of NER. The patients suffering from these conditions have high incidences of cancers, illustrating a link between defects in DNA repair and cancer. Another group of disorders that have defects in DNA repair are characterized by premature aging, that is, that the patients appear much older than their chronological age. These diseases include Cockayne syndrome, Werner syndrome, and other forms of progeria. Some diseases are characterized by a preponderance of genomic instability, likely also linked to DNA repair defects. These include Bloom syndrome, ataxia telangiectasia, and Nijmegen breakage syndrome. All of the above conditions are rare and this strengthens the notion that DNA repair is an essential process and if severely defective, life cannot be sustained.

1.10 Perspectives

DNA repair is a complex and fascinating process and it is very interactive with other DNA metabolic processes. It is tightly linked to the transcription process via the basal transcription factor TFIIH, which participates in both processes. It is also tightly linked with DNA replication and with a number of signal transduction pathways. An age-associated decline in DNA repair could explain why older individuals suffer from age-associated diseases and become highly susceptible to cancer. Increased insight into the mechanisms of DNA repair may also lead to therapeutic interventions in the future, for example by enhancing the DNA repair activity.

Keywords

RNAP Mutant (in TS)
RNA polymerase mutants that rNTPs and 3′-dNTPs incorporate uniformly and efficiently.

MALDI-TOF-MS Sequencing
Mass spectroscopy of chain-terminated nucleotide molecules with MALDI-TOF-MS.

TS
Transcriptional Sequencing.

Transcriptional Sequencing (TS) is a novel DNA sequencing method based on the chain termination method using RNA Polymerase (RNAP). Transcriptional sequencing differs considerably from conventional cycle sequencing methods using DNA Polymerases (DNAPs) with 2′-deoxyribonucleotide triphosphates (2′-dNTPs) and 2′, 3′-dideoxyribonucleotide triphosphates (2′,3′-ddNTPs). The TS method employs a modified T7, T3, or SP6 RNAP with ribonucleotide triphosphates (rNTPs) and 3′-deoxyribonucleotide triphosphates (3′-dNTPs) as substrates and terminators, respectively, and the T7, T3, or SP6 promoter sequence is used as initiation site instead of the primer sequence. The characteristics of RNAP allow TS to be conducted under conditions that are substantially different from conventional cycle sequencing using DNAP. In TS, the reaction is performed isothermally (at 37 °C) and is stable

with high processivity. Transcriptional sequencing can be applied to various amounts of double-stranded DNA template because RNAP produces a large number of transcribed RNA molecules and the quantity of product is limited by the quantity of substrate rather than that of the template. Furthermore, in direct sequencing using TS, PCR products do not need to be purified before the sequencing reaction because RNAP requires neither 2′-dNTPs nor single-stranded PCR primers, but polymerization is primed using specific double-stranded promoters and rNTPs. This characteristic feature ensures that even highly GC-rich DNA templates can be sequenced effectively. Transcriptional sequencing is also applicable to MALDI-TOF-MS DNA sequencing owing to the stability of the RNA polymer against fragmentation caused by laser ablation. Thus, TS differs considerably from conventional cycle sequencing methods using thermostable DNA polymerases, but should complement such methods in numerous practical applications.

1 Introduction

There are two major families of enzymes responsible for polymerization of nucleic acids *in vivo*; DNA polymerases (DNAPs), which are responsible for DNA replication, and RNA polymerases (RNAPs), which are responsible for transcription. DNA polymerases produce double-stranded DNA (dsDNA) using a single-stranded DNA (ssDNA) template and consume deoxyribonucleotide triphosphates (dNTPs) as substrate. On the other hand, RNAPs produce RNA strands from a dsDNA template and consume ribonucleotide triphosphates (rNTPs) as substrate. Most modern sequencing kits utilize the Sanger method with DNAP and 2′,3′-dideoxyribonucleotide triphosphate (2′,3′-ddNTP) terminators bound to a dye, and in conjunction with development of DNAP mutants, such as mutated *Taq* DNAP (Thermosequenase, FS *Taq* etc.), and energy transfer dye, sequencing accuracy has been improved substantially and large amounts of data have been produced.

In principle, RNAPs can be also applied to the chain termination method, using 3′-deoxyribonucleotide triphosphates (3′-dNTPs) as terminators. Axelrod V.D. and Kramer F.R. reported the first trial of the chain termination method using T7 RNAP in 1985, but the technique was not developed further. On the other hand, cycle sequencing based on *Taq* DNAP has been widely used for sequencing kits. The reasons why sequencing with RNA and RNAP is not widely used are likely related to concerns regarding the instability and the strong secondary structure of RNA chain termination molecules, which would interfere with sequencing reaction and electrophoresis. However, in reality, both the reaction and subsequent electrophoresis are relatively simple to perform. Furthermore, transcriptional sequencing (TS) has numerous advantages over conventional cycle sequencing owing to the characteristic features of RNAP, such as the ability to sequence GC-rich regions that usually appear as sequencing gaps with DNAP-based sequencing kits, applicability to MALDI-TOF-MS (Matrix-assisted laser desorption/ionization time-of-flight

mass spectrometry) mass spectrometry for sequencing, which gives better stability of chain termination products than DNAP-based sequencing, and because there is no need for either large amounts of template molecules or purification of templates for direct sequencing.

Here, we describe the history, development, and characteristic features of ''Transcriptional Sequencing'' based on chain termination methods using modified RNAP.

2 Components of Transcriptional Sequencing

2.1 Principle

Transcriptional sequencing is a DNA sequencing method that uses RNAP. This method is based on the chain termination method, and uses rNTPs as substrate and 3′-dNTPs as terminators. Figure 1 shows a schematic comparison of conventional cycle sequencing and TS. With cycle sequencing, programmed repetitive changes in the reaction temperature are employed. One set of programmed temperature changes is called a *cycle*, and there are typically three steps in one cycle; annealing, elongation, and denaturation. DNA oligo-primers are allowed to anneal during the first step, DNAPs then incorporate 2′-deoxyribonucleotide triphosphates (2′-dNTPs) to elongate the primers until 2′, 3′-dNTPs are incorporated or until the reaction terminates spontaneously, and finally, the Sanger reaction products and primers are dissociated from template during the denaturation step. In contrast, there is only one step for the TS method; transcription (at 37 °C). Transcription is initiated from the promoter (T7, T3, or SP6) on dsDNA and transcripts elongate until RNAPs incorporate 3′-dNTPs or until the reaction terminates spontaneously. Reaction products are released

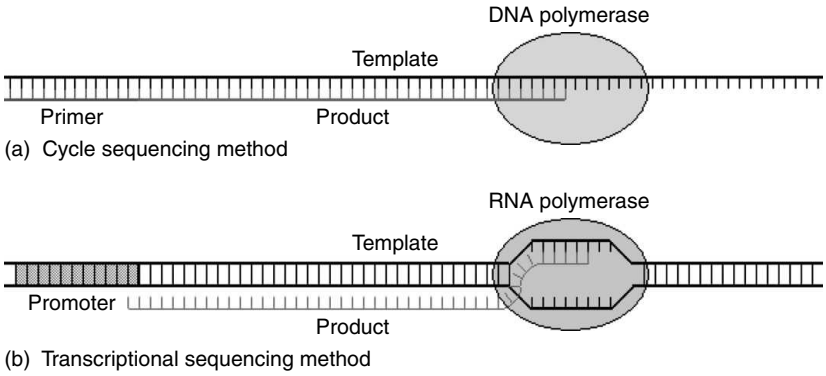

Fig. 1 Schematic comparison of TS and cycle sequencing methods. (a) Cycle sequencing method. Black line indicates template (ssDNA). Blue line indicates primer, which is elongated by DNAP to give the reaction product (red line). Elongation of product terminates either spontaneously or when DNAP incorporates a terminator (2′, 3′-deoxyribonucleotide triphosphate). (b) TS method. Black line indicates template (dsDNA). Gray zone indicates promoter region, which is the starting point of the transcript (red line). Elongation of product terminates either spontaneously or when RNAP incorporates a terminator (3′-deoxyribonucleic triphosphate). (See color plate p. xxiv).

when RNAP separates from the template. RNA molecules in the reaction mixture are separated by length and are detected by fluorescence or mass spectrometry.

2.2 Enzymes

Because of the low efficiency and nonuniform incorporation of substrates used by wild-type RNAP, mutants were designed in order to achieve accurate DNA sequences. We designed such mutants by carefully referring to the 3D structure of DNAP.

2.2.1 Enzymological Strategies for Development of Novel Mutant Polymerases for Sequencing

Cycle sequencing systems based on *Taq* DNAP have been developed in order to improve the readable length and accuracy of sequencing. In developing a mutant enzyme, information regarding the 3-D structure of DNAP is very useful. In particular, the common structure for DNAP indicates the amino acid residues that could be substituted to confer desirable properties on the polymerase. For cycle sequencing, mutant *Taq* DNAPs, such as Thermosequenase, FS *Taq* DNAP, and Therminator DNAP, have been developed to allow incorporation of fluorescence-labeled 2′,3′-ddNTP substrates efficiently and uniformly.

RNA Polymerases play a fundamental role in the transcription process in bacteriophages. In particular, T3, T7, and SP6 phages synthesize phage-encoded RNAPs after infecting the host cell. These RNAPs recognize their own phage-specific promoter sequences that are not encoded in the host genome sequence. The specificity and high processivity of these polymerases have led to the development of plasmid vectors that allow transcription of cloned DNA fragments downstream of the phage promoter. In addition, phage RNAPs always initiate transcription at a single and fixed position within the promoter region, and thus, these transcripts have a common 5′ end. This property of RNAPs allows us to apply this type of enzyme to chain termination DNA sequencing. The first trial to produce sequence data using the chain termination reaction with T7 RNAP was reported in 1985 (Axelrod V.D. and Kramer F.R.). The pattern obtained with T7 RNAP using internal radio-labeled nucleotide was quite similar to the analogous ladder pattern with various intensity bands using Klenow fragments. However, the intensity of the T7 RNAP ladders was much less uniform than that of the T7 DNAP. This property is undesirable for accurate sequencing and is clearly due to the strong preference of RNAP to incorporate natural nucleotides and terminators. Development of the T7 RNAP mutant that incorporates natural ribonucleotide substrates and terminators in an equal ratio was essential in order to establish TS for practical use.

For the above reasons, we planned a series of mutations to develop a T7 RNAP mutant. According to mutant characterization and three-dimensional structure analysis, the catalytic domain of T7 RNAP is separated into the T7 promoter binding region (674–752 aa), Mg^{2+} binding sites (Asp537, Asp812), and essential regions for polymerase activity (motif A, motif B, motif C). When we began developing the mutant RNAP for TS, two mutants were found to recognize the 2′ or 3′ hydroxy groups in nucleotide substrates of RNAP and DNAP (*Taq* polymerase), respectively. One of these is T7 RNAP Y639F. Tyr639 is located in the active site and has been reported to be the discrimination site for 2′-OH groups in T7 RNAP. The Y639F mutant retains both DNAP and RNAP activities and is unable to discriminate

between rNTPs and 2′-dNTPs. This mutant analysis suggests that the hydroxyl group in the tyrosine residue binds the 2′-site of dNTPs (hydrogen atom) within the pocket of RNAP in order to incorporate the 2′-dNTP substrates. Therefore, to develop a novel mutant that incorporates the 3′-dNTP, the amino acid that recognizes the 3′-OH of rNTPs should be mutated to a hydroxyl group. Mutation from phenylalanine to tyrosine or vice versa improves affinity for the 2′-OH group of 2′-dNTPs in the Y639F mutant and for the 3′-OH group of 2′,3′-ddNTPs in *Taq* polymerase or Thermosequenase, as described in the reverse compensation theory of 2′- and 3′-OH groups proposed by Tabor and Richardson.

The other mutant is T7 RNAP M635A. Originally, Met635 of T7 RNAP was thought to be the interaction site for the 3′-OH group, suggested both by homology analysis with Klenow fragments and by mutation analysis, where affinity for rNTPs decreased when Met635 was substituted with Arg635. However, there has been no direct proof that the M635A recognizes the 3′-OH group any more efficiently than Y639F. Thus, an RNAP mutant that incorporates 3′-dNTPs efficiently has not yet been reported, and we subsequently began developing an RNAP mutant for TS, designated transcriptional sequenase (TSase).

On the basis of the above information, we initially looked for a phenylalanine residue located in the nucleotide-binding pocket. To design the TSase mutant, we paid particular attention to the 3D structure of T7 RNAP in order to identify the catalytic domain for nucleotide binding.

In the catalytic domain, we identified Phe644, Phe646, Phe667, Phe782, Phe773, and Phe882 and we conducted site-directed mutagenesis in order to change Phe644, Phe646, Phe667, Phe782, and Phe773 to Tyr. All mutant RNAPs were expressed in *Escherichia coli*, and purified, and their catalytic activities for incorporation of 3′-dNTP were analyzed. The 3′-dNTP incorporation activity of F644Y and F677Y were 100-fold greater than that of wild-type polymerase. Figure 2 shows the sequence alignment of the mutation sites of T7 RNAP mutants in comparison with *E.coli* polymerase, *Taq*, and T7 DNAP. The pocket for nucleotide substrates of RNAP is formed

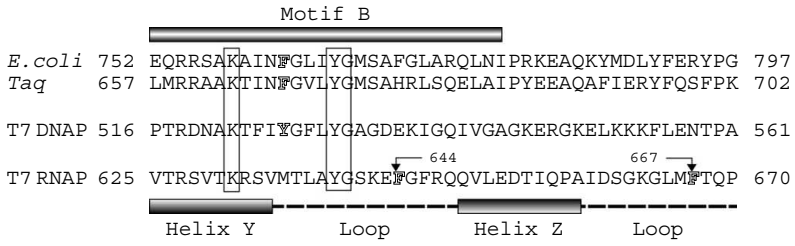

Fig. 2 Mutation sites of the T7 RNAP mutant at regions including motif B, and a comparison with several DNAPs. Sequences were taken from *E. coli* DNA polymerase I, *Taq* DNAP, T7 DNAP, and T7 RNAP. Strictly conserved positions in all polymerases are boxed, and the residues responsible for discriminating between 2′- and 3′-OH groups are indicated by white letters. The upper bar indicates motif B as one of the highly conserved regions, the lower bars and the dotted line indicate the helix and loop structure of T7 RNAP. The T7 RNAP mutants shown in this figure were designated F644Y and F667Y.

by the HelixY–loop–HelixZ–loop region. Phe644 and Phe667, which access the 3′-OH of nucleotide substrates in the polymerase domain, are located in this region.

We have designed T3 RNA polymerase mutants according to the above principles. In T3 RNA polymerase, Phe645 and Phe668 are located in this HelixY–loop–HelixZ–loop region, and the mutants F645Y and F668Y were found to incorporate 3′-dNTP much more rapidly than the wild-type polymerase.

Following the construction of the above mutants, Nippon Gene Tech. Co, Ltd. developed newly mutated RNAPs in order to improve the fidelity and efficiency of transcription. The features of the newly constructed mutants resulted in high S/N signals and were suitable for capillary-based DNA sequencers.

2.2.2 Promoter Recognition and Binding of T7 RNA Polymerase to DNA Template

Promoter sequences for T7 RNAP and related phage RNAPs consist of a 23-bp consensus sequence that extends from −17 to +6.

	−17	−10	−5	+1	+5
anti-sense strand	TAATACGACTCACTATAGGGAA				
sense strand	ATTATGCTGAGTGATATCCCTT				

This promoter sequence is similar to the truncated promoters for bacterial RNAP, having an upstream binding region of a TATA box element closer to the site of initiation. The phage promoter consists of two functional regions. One is the RNAP binding region located upstream from position −6 and the other is the initiation region for transcription located downstream from position −6. The roles of these two domains were demonstrated by experiments in which mutations at the binding domain decreased the affinity of the polymerase for the promoter, but had little effect on the initiation rate. Conversely, mutations in the initiation region had a significant effect on the kcat (Catalysis constant or turnover number) of the initiation rate. Mutations in this region vary the degree of abortive initiation, and thus, product yield decreases considerably. After polymerase binds to the promoter, both strands of DNA template are dissociated for the initiation of transcription.

2.2.3 Initiation

At the initiation of RNA synthesis by all RNAPs, an abortive transcription cycle usually proceeds before the elongation stage begins. RNAP can engage in multiple rounds of abortive initiation in which short RNA products are continuously synthesized and released. The frequency of this abortive initiation, the length of the RNA produced, and the efficiency with which the polymerase enters a stable elongation stage depends on numerous factors. During all stages of transcription, there exists a competition between incorporation of successive nucleotides (elongation) and dissociation of the RNAP–DNA–RNA complex.

2.2.4 Termination

The mechanism of T7 RNA polymerase termination has been less studied than the mechanism of transcription initiation. T7 RNAP does not terminate efficiently at the thr attenuator, which terminates *E. coli* polymerase with about 90% efficiency; T7 RNAP terminates at about 40% efficiency. Even at the T7-Tf terminator, termination efficiency is 66%. The most efficient

known terminator is the 7-bp sequence in the PTH (human prepro-parathyroid hormone) gene, which has an efficiency of above 90%.

2.2.5 Slippage

Transcriptional slippage, particularly in the TS procedure, is a phenomenon in which extra U residues are incorporated during the elongation. The slippage of TS frequently occurs in A or T homopolymeric regions, and particularly when there are continuous A or T regions of approximately 10 bp. Once slippage occurs, the sequencing pattern clearly becomes erroneous. The slippage described above is an intrinsic characteristic of wild-type RNAPs derived from the evolutional process. With regard to TS, such a characteristic is a disadvantage when sequencing the A or T homopolymeric sequences that preferentially appear in noncoding regions.

2.3 Composition and Methods for DNA Sequencing by TS

There are several available reagents that can be used to obtain accurate sequences with mutated RNAP. Here, we discuss those reagents briefly.

2.3.1 Mutant T7 RNA Polymerases

TS has a threshold for the enzymatic units of T7 RNAP necessary for numerous initiation cycles, some of which continue on to transcription. In order to increase the commercial viability of TS kits, the required amount of enzyme should be produced at low cost and at high purity. In this sense, the F644Y mutant is ideal when compared to F667Y because F644Y can be produced at high yield and with high purification efficiency.

2.3.2 Polyamine

In various *in vitro* enzyme reactions, polyamines such as spermine and spermidine have been widely used as counterions for nucleic acids. They have also been shown to stimulate RNA transcription by DNA-dependent RNAPs from phages. Therefore, we have attempted to optimize sequencing conditions by screening a variety of polyamines for increases in transcription rate, and have found that both spermidine and 1,8-diamino octane exhibited significant improvements in RNAP transcriptional activity.

2.3.3 Pyrophosphatase

Incorporation of each rNTP (or 2′-dNTP) into the polynucleotide chain by RNAP or DNAP releases an inorganic pyrophosphate (PPi) molecule. Inorganic pyrophosphate molecule degrades polynucleotide products by attacking the 3′-terminal internucleotide linkage. This phenomenon is called *pyrophosphorolysis* and it generates NTPs or dNTPs. This phenomenon is the reversal of polymerization. The enzyme inorganic pyrophosphatase (PPase) cleaves inhibitory pyrophosphate into monophosphate, which has less ''pyrophosphorolysis'' activity. Therefore, addition of PPase is necessary to ensure accurate sequence data, and it produces patterns with higher, sharper, and more uniform peaks (Fig. 3). The effects of PPase in improving the electropherogram can also be seen in chain termination using DNAP.

2.3.4 GMP as an Initiator and Modified NTPs as Substrates

Electropherograms are distorted by mobility shifts due to the secondary structure of chain termination products, particularly those of G–C stretches. To overcome this problem, we used the nucleotide analogs rITP or 7-deaza-GTP in place of

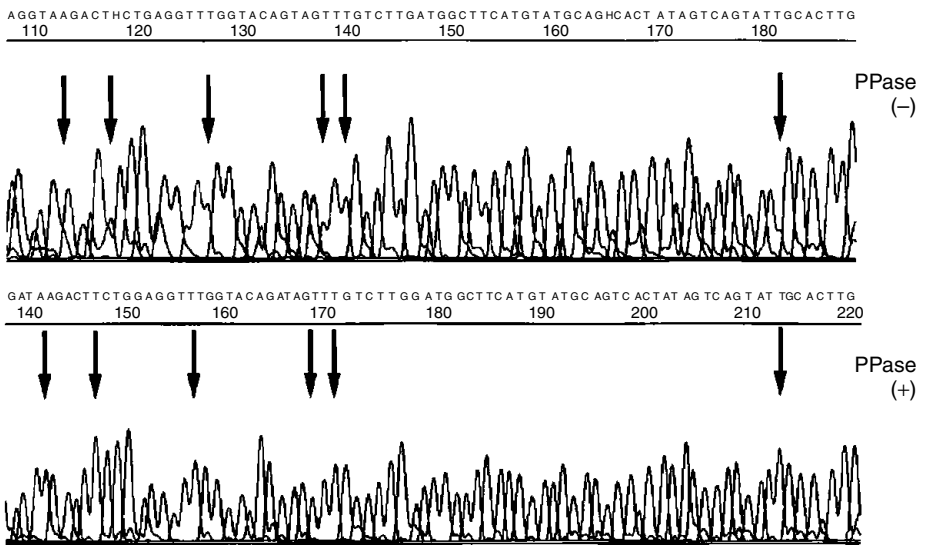

Fig. 3 Effect of PPase addition on transcriptional sequencing with F644Y T7 RNAP and four fluorescent-labeled terminators. Sequencing was carried out with unpurified human TSH-b cDNA PCR products as a template in the absence (–) or presence (+) of PPase. Arrows in both spectra are equivalent and indicate bases that are sensitive to pyrophosphorolysis.

rGTP. These nucleotide analogs proved to be very successful for accurate sequencing. Although these analogs can be substituted for GTP during chain elongation, they cannot be substituted for GTP during the initiation steps of transcription. Consequently, the use of rITP or 7-deaza-GTP would reduce the efficiency of transcription initiation. This problem can be overcome by addition of GMP to the reaction mixture. GMP is then incorporated first by RNAP, and then initiation efficiency increases dramatically.

2.3.5 DNA Templates

There are numerous widely used plasmid vectors that contain the corresponding T7, T3, or SP6 promoters. The most recent commercially available cloning vectors contain two different phage promoters flanking a multiple cloning site at both ends. Usually, one of phage promoters is the T7 RNAP promoter. In general, by digesting the template with a restriction enzyme that cleaves distal to the phage promoter on the other side, a run-off transcript of a defined size can be synthesized. These polymerases have been shown to be active on linear templates. However, supercoiled templates with slightly less activity of RNAP than linear templates can be also used in order to save the labor associated with preparation of linear templates.

Template preparation requires highly pure DNA that is free of ribonucleases. All RNase must be removed before using prepared DNA as a template for TS, and thus, most preparation protocols include an RNase treatment. In addition, T7 promoter-containing cloned or PCR-generated DNA can be used as a template.

Templates generated by polymerase chain reaction (PCR) having a promoter-tagged primer along with the sequence of interest allow production of RNA fragments for sequencing.

3 Remarkable Properties of Transcriptional Sequencing

3.1 Isothermal and Rapid Reaction

Because the transcription is an isothermal process, TS occurs at a constant temperature (37 °C) and does not require a thermal circler. Furthermore, the strong processivity of RNAP enables the reaction time to be greatly reduced. For standard reactions, the reaction time is 1 h, which is half that of standard cycle sequencing reactions.

3.2 Wide Dynamic Range

One of the most advantageous properties of TS is that it requires smaller amounts of DNA template when compared to conventional cycle sequencing. The amount of chain termination product is limited by the amount of template DNA in DNAP-dependent sequencing but by the amount of substrate in TS. In cycle sequencing, the chain termination products compete with primers for annealing with limited amounts of template, and the templates primarily anneal with the reaction products rather than the primer because of their size. In order to avoid this problem and increase reaction product, a large amount of primer might be added to reaction mixture. However, in those situations, misannealing of primer would frequently occur and the electropherogram pattern would be disordered. Therefore, number of molecules of sequence product cannot greatly exceed the number of molecules of template DNA. On the other hand, RNAP initiates transcription from a double-stranded promoter site, and one template DNA molecule can produce a large number of TS products. The TS reaction is terminated by the exhaustion of substrates. For this reason, for small amounts of template, better sequence quality has been obtained with TS rather than with cycle sequencing. In the current TS protocol, 10 ng of plasmid DNA can produce a high quality of electropherogram, while no signal can be detected using the conventional single dye terminator method.

3.3 Readability of GC-rich Templates

A remarkable feature of TS is that GC-rich templates can be easily sequenced. Usually, GC-rich templates are difficult to sequence by cycle sequencing methods because single-stranded DNA molecules with high GC contents tend to form secondary structures, such as stem loops, and, because DNAP uses ssDNA as a template, secondary structures of template DNA have a serious effect on elongation, resulting in sudden termination of polymerization. Such termination causes sudden stops in the sequence signals on electropherograms. On the other hand, ds-DNA, whose secondary structure is less affected than that of ssDNA, is used as template in TS. In Fig. 4, the upper electropherogram (a) is the pattern for conventional cycle sequencing. The peak pattern is weakened and terminated in the middle of electrophoresis, where the content of GC is high. The lower electropherogram (Fig. 4b) is that produced for TS. No such effect is observed in this electropherogram,

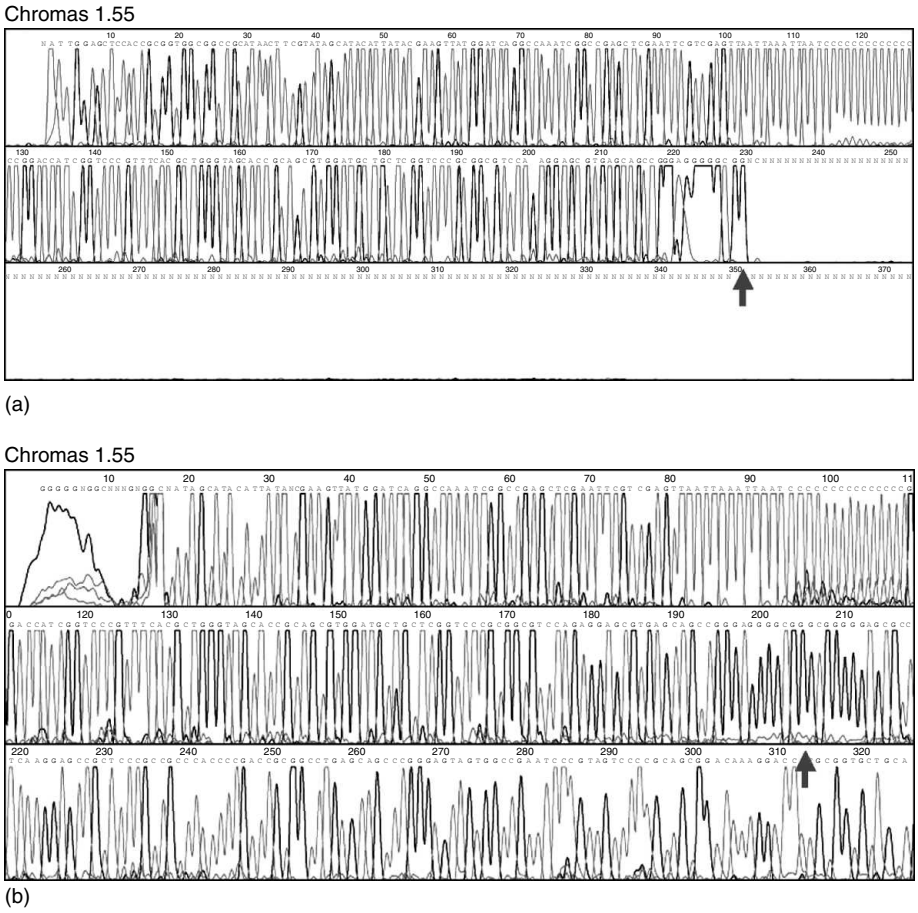

Fig. 4 Comparison of electropherograms (a) Electropherogram using a Big Dye Terminator ver 1 kit. Peaks suddenly disappear at the point indicated by the arrow. (b) Electropherogram using TS (CUGA® 7 sequencing kit) Arrow indicates the termination point shown in (a), and peaks continue beyond this point. Shibata K., et al., Practical application of transcriptional sequencing for GC-rich templates, *J. of Struct. Funct. Genomics.*, 2003, **4**(1), p. 35, by permission of Kluwer academic publishers.

thus, clearly demonstrating the applicability of TS to GC-rich regions.

This property is partly due to the origins of RNAP. Originally, RNAP evolved to initiate gene transcription from the 5′ site, where GC is preferentially located. GC-rich sequences, such as CpG Islands, were used for transcriptional control in the evolutional history of vertebrate genes. Therefore, it is very reasonable that GC-rich regions are more easily sequenced by TS than by cycle sequencing.

4 Detection of Transcriptional Sequencing Products

TS based on RI labeling was reported in 1985. Following these early reports,

however, none of the attempts to produce a clear TS pattern were successful until the four-colored fluorescence terminator appeared in 1995.

4.1 BODIPY-labeled Terminators for Auto Sequencers

Nippon Gene Tech. Co, Ltd. has developed fluorescent-labeled terminators using four colored BODIPY® fluorescent dyes. The synthetic terminators are a set of four fluorescent BODIPY-dye terminators. The four BODIPY dyes BODIPY FL, BODIPY R6G, BODIPY 564/570, and BODIPY 581/591 are bound with spacers to 7-deaza-3′-GTP, 7-deaza-3′-ATP, 3′-UTP, and 3′-CTP, respectively. The dye set and enzymes (T7 or T3 RNAP mutant) are now packaged together in one kit called the CUGA® sequencing kit, which is compatible with almost all sequencers currently in use. Chain termination RNA products can be detected in the same way as DNA ladders using conventional DNA sequencing kits, and the ladder pattern can be analyzed using the manufacturer-supplied basecaller.

4.2 Rhodamine-labeled Terminators for DNA Sequencing

Wako Pure Chemical Industries, Ltd. has synthesized fluorescent-labeled terminators. The synthetic terminators are a set of four fluorescent rhodamine-dye terminators. The four rhodamine dyes TMR, R6G, ROX, and R110 are bound with spacers to 3′-UTP, 3′-ATP, 3′-CTP, and 3′-GTP, respectively.

4.3 3′-dNTP Terminators for Mass Spectroscopy

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry has developed into a rapid, accurate, and sensitive method for the mass analysis of high molecular weight synthetic and biological polymers, including nucleotide acid molecules. This method enables rapid DNA sequencing using the chain termination method. This method is advantageous because it does not require separation matrices or fluorescent dyes, in contrast to conventional separation methods based on electrophoresis. However, despite these advantages, MALDI-TOF-MS cannot replace conventional electrophoresis, particularly for *de novo* sequencing, because of its short read length (less than 100 bp). This limitation is due to salt contamination and fragmentation of the polynucleotide by laser ionization.

Fragmentation occurs at the phosphodiester bond. In one hypothesis of DNA fragmentation, protonation of the nucleobase during the MALDI process is induced. The N-glycoside linkage at 1′-carbon becomes unstable, which is followed by base loss and cleavage of phosphodiester backbone. It has been shown that electron-withdrawing groups such as 2′-hydroxyl or 2′-fluoro groups stabilize the N-glycosidic bond, impede fragmentation, and thus, extend the accessible mass range. Because of the higher electron-withdrawing properties at the 2′-site of RNA, fragmentation of RNA polynucleotides is expected to reduce considerably. This property is advantageous for TS using MALDI-TOF-MS. In fact, TS using modified SP6 RNAP has been reported (Fig. 5), thus demonstrating the enormous potential for TS to apply MALDI-TOF-MS sequencing.

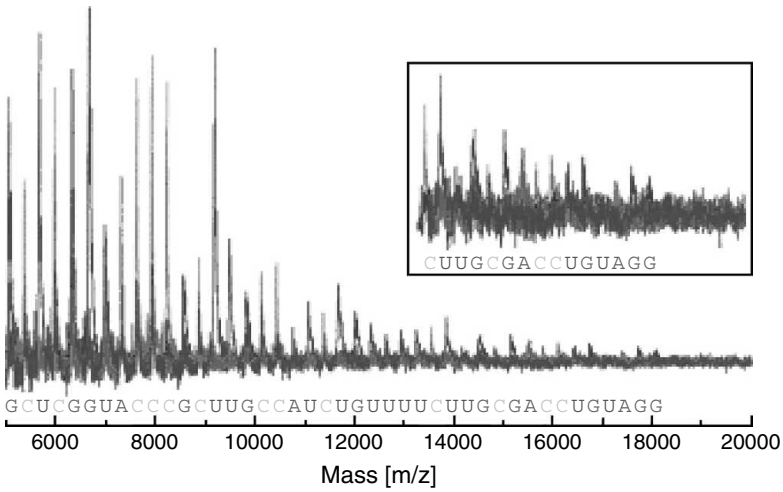

Fig. 5 Products of RNA chain termination analyzed by MALDI-TOF-MS. A nicked form of phage SP6 RNAP was used for chain termination reaction. MALDI-TOF-MS of reaction product allowed DNA sequence determination of 56 bases. Kwon Y, et al., DNA sequencing and genotyping by transcriptional synthesis of chain-terminated RNA ladders and MALDI-TOF mass spectrometry, *Nucleic Acids Res.*, 2001, **29**(3), e11, by permission of Oxford University Press.

5
Standard Protocol for Template Preparation, Reaction, and Electrophoresis

5.1
Template Preparation, Reaction, and Purification

RNase should be excluded in order to obtain high-quality sequences. For this reason, additional treatment is required when compared to conventional DNA sequencing methods. The procedure below is a rigid protocol for preparing DNA templates for TS.

1. Extract plasmid using standard alkaline lysis method.
2. Dissolve in 50 µL of TE (10 mM Tris-HCl (pH 8.0) and 1 mM EDTA).
3. Add 1 µL of RNase A solution (1 µg/µL) and store at room temperature for 30 min.
4. Add an equal volume of PEG solution (13% polyethylene glycol 6000 and 1.6 M NaCl), mix well, and then leave on ice for 20 min.
5. Centrifuge at 15 000 rpm for 20 min at 4 °C.
6. After removing the supernatant, rinse with 70% ethanol solution.
7. Dissolve pellets in 100 µL of TE and extract with phenol, phenol : chloroform, and then chloroform.
8. Add 200 µL of ethanol to the extracted solutions and leave tubes on ice for 20 min.
9. Centrifuge at 15 000 rpm for 20 min at 4 °C.
10. Dry for 10 min at room temperature.
11. Dissolve in 50 µL of TE.

Note: The RNase solutions supplied with commercially available plasmid preparation kits (ex. Qiaprep plasmid preparation kit from Qiagen Inc.) are not suitable for

preparation of plasmid DNA as a template for TS analysis.

For high-thoughtput sequencing, template preparation without RNase treatment is possible. Using the CUGA® kit, the reaction protocol is as described below.

1. Mix 4 µL of RNase-free plasmid DNA and 4 µl of 5x reaction buffer, 1 µL of 8 mM $MnCl_2$, 2 µL of NTP/Terminator mixture, and 8 µl of ddH_2O.
2. Add 1 µL of enzyme solution.
3. Add 1 µL of template.
4. Mix gently and incubate at 37 °C for 60 min.
5. Purify by EtOH precipitation.

5.2 Direct Sequencing without Purification

The most useful application of TS is direct sequencing. Direct sequencing is a method that allows PCR products to be sequenced directly after amplification from genomic DNA, BAC, plasmid DNA, or other DNA sources. In conventional dye terminator sequencing methods, PCR primers and 2′-dNTP substrates have to be removed in order to prevent mispriming and to preserve the ratio between the four 2′-dNTPs in subsequent chain termination reaction steps. On the other hand, in TS, PCR products amplified with T7 and T3 promoter-tagged primers do not need to be removed prior to sequencing because RNAP can recognize neither the single-stranded primers nor 2′-dNTPs. Therefore, PCR-direct sequencing can be achieved by addition of RNAP and appropriate reagents, without any purification steps after PCR amplification.

5.3 Electrophoresis

Although the RNase-free condition is theoretically essential, it seems that special treatment of the separation matrix and electrophoresis buffer to remove RNase are not required for TS. Sample loading on the gel slots and electrophoresis can be conducted in the same manner as for conventional DNA sequencing.

6 Future Applications of TS

6.1 Modification of Substrate

Numerous modified NTPs are incorporated by wild-type T7 RNAP. In particular, the Sp isomer of the [α-S]NTPs [nucleoside 5′-*O*-(1-thio-triphosphate)] is a good substrate for T7 RNAP. The Sp isomer contains a sulfur atom bound to the phosphate in the phosphodiester bond, and this sulfur atom is located on the side opposite the 2′-site of the sugar. This substrate set might make TS develop into a reaction system with higher performance. Moreover, if novel T7 mutants that incorporate the Sp isomer of the [α-S]NTPs at higher rates than normal NTPs could be designed, reaction speed and sensitivity would increase to levels above those in the current system.

6.2 Modification of Dye

Current TS dye sets for auto sequencers employ ‘‘single’’ dyes. The energy transfer mechanism has been used for dyes binding to terminators in cycle sequencing. These dyes have achieved better signal to noise ratios, resulting in more accurate and longer sequences. This technology has helped to realize the current genome projects (human, mouse, etc.) by substantially expanding the sequencing capacity because of its remarkable properties, for

example, readability of GC-rich regions. Energy transfer dyes for use with TS and substrate analogs will appear in the near future.

6.3 Chemical Modification of Substrate for Mass Spectroscopy

Reduction of fragmentation is important for yielding longer sequences with MALDI- TOF-MS. Chemical modifications of the nucleoside or backbone are able to reduce attacks to the N-glycosidic bond and block cleavage of the phosphodiester bond. Our group examined various nucleotide analogs for MALDI-TOF-MS. Fluorine at the 2′-position of ribose or 2′-arabino-ribose highly reduces fragmentation, and moreover, backbone modification would be effective in blocking backbone cleavage. We investigated the effects of such changes using riboses, as shown in Fig. 6. S-RNA is a phosphorotioate oligonucleotide that is known to be a biostabilized nucleotide backbone owing to its nuclease resistance. We chemically synthesized 10, 20, and 30 mer oligos and used two types of matrix, 3-hydroxypicolinic acid (3-HPA) and trihydroxyacetophenone (THAP), in our experiments. The mass spectra of those oligos are shown in Fig. 7. These spectra suggest that phosphorothioate oligonucleotides are more resistant to signal drop-off than other native or chemical-modified ribonucleotides. The sulfur in the backbone is believed to prevent cleavage of the oligonucleotides.

6.4 Lab on a Chip

Because of miniaturization technologies, such as lithography, it may be possible to conduct experimental procedures on small chips. With this type of technology, once all of the samples are subjected to separation, the samples could not be recovered from a chip. Two basic conditions are preferred for such enzymatic reaction systems using lab-on-chip technology. One is that the reaction is isothermal, and the other is that the samples cannot be subjected to separation or purification steps, such as

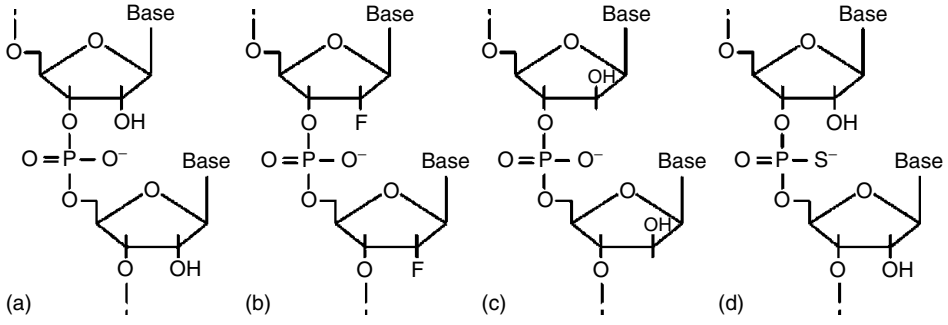

Fig. 6 Native RNA and modified RNAs used for experiments against fragmentation. (a) native RNA, (b) 2′-fluoro-RNA, (c) 2′-arabino-RNA, (d) S-RNA. RNA and S-RNA were purchased from GENSET OLIGOS (Kyoto, Japan). 2′-fluoro-RNA and 2′-arabino-RNA were purchased by TriLink BioTechnologies (San Diego, CA). Sequence of RNA and S-RNA oligos are d(GAUCUCAGCU), d(GAUCUCAGCUCUAAUGCGGU), d(GAUCUCAGCUCUAAUGCGGUUCGAUAA-AUC) and d(GAUCUCAGCUCUAAUGCGGUUC-GAUAAAUCCACUGUGAUA). Sequences of 2′-fluoro- and 2′-arabino-RNA were d(C)*n* (*n* = 10, 20, or 30, respectively).

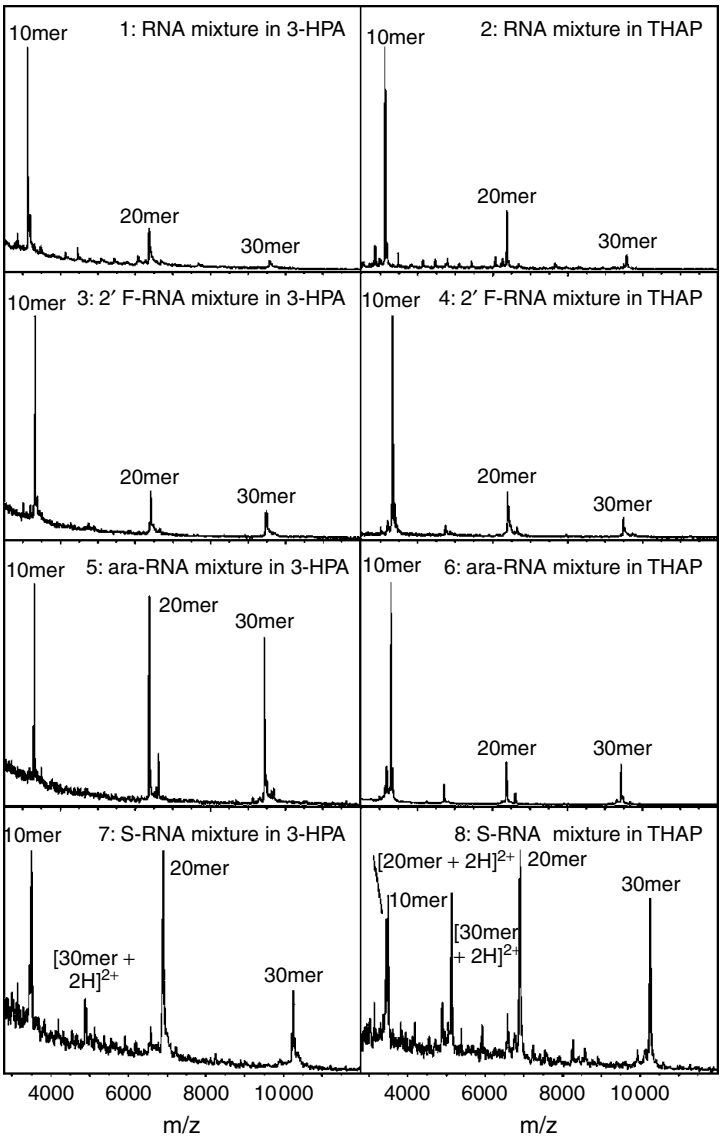

Fig. 7 UV-MALDI mass spectra of prepared oligos using 3-HPA (3-hydroxypicolinic acid) or THAP (trihydroxyacetophenone) matrixes.

centrifugation, ethanol precipitation, and phenol extraction. Thus, samples should be ready for sequencing in a detection system, such as fluorescence detection or mass spectrometry. TS meets these criteria perfectly, and we are hopeful that TS can be applied to lab-on-chip sequencing in the $1000 genome project.

Finally, as explained in this article, the principles of the chain termination are the same in both TS and cycle sequencing; however, the characteristic properties

differ substantially, but are complementary, between these two systems. This is primarily due to the enzymatic properties of DNAP and RNAP that developed during the evolutional process. Practical TS systems have been recently developed, and there are numerous possible applications in a wide variety of fields for these systems. We hope that this article aids in the understanding of TS and that further applications will be developed on the basis of TS methodology.

Keywords

Melting Temperature
The temperature at which nucleic acid double strands dissociate into single strands. The melting temperature is determined by properties of the oligonucleotide such as sequence or chemical modifications.

Oligodeoxynucleotide
An oligonucleotide consisting of 2′-deoxynucleotide moieties.

Oligoribonucleotide
An oligonucleotide consisting of 2′-hydroxynucleotide moieties.

Phosphoamidite
The building block for automated chemical synthesis of oligonucleotides.

Phosphodiester Linkage
The phosphate linkage connecting to nucleoside moieties within an oligo or polynucleotide.

Protection group
Groups that protect functional groups such as amino or hydroxyl groups against unwanted side reactions during the course of synthesis.

Oligonucleotides are important tools in biochemistry and in molecular and cellular biology. Moreover, oligonucleotides such as antisense oligonucleotides or small interfering RNAs hold promise as therapeutic agents to combat human disease. The main prerequisite for the wide use of oligonucleotides was the development of efficient and robust synthesis protocols, which allow for the production of oligonucleotides at a wide range of synthesis scales with very affordable costs. Furthermore, the chemical synthesis permits the site-specific introduction of chemical modifications such as phosphate, sugar or base derivatives, which affect the chemical and biological properties of oligonucleotides. Oligonucleotides are used in molecular biology for sequence detection and determination as well as in cell biology and molecular medicine for functional genomics, target validation, and drug development. This review describes recent advancements of oligonucleotide synthesis and discusses several common applications of oligonucleotides.

1 Introduction

Nucleotides can form homopolymers and heteropolymers with chain lengths ranging from as short as a dinucleotide or only a few nucleotides to extremely long chains that approach the length of long viral genomes or even whole genomes or chromosomes of lower and higher organisms. Depending on their sugar chemistry, nucleotides may form either ribonucleic acids (RNA), deoxyribonucleic acids (DNA) or they may be chemically modified. Oligomeric nucleic acids, that is, oligonucleotides, are of particular relevance and importance as tools and drugs in molecular biology and biomedicine. Oligonucleotides have been the subject of an extremely large variety of chemical modifications that are meant to confer favorable biochemical and biological properties. Improving their chemistry and adapting the chemistry to the specific requirements for their use is crucial to successful application.

The fields of research and development and the range of purposes for which oligonucleotides are used are extremely wide. Conversely, basic considerations and principles regarding the synthesis and the use of oligonucleotides are limited. Thus, it seems to be appropriate to describe fundamental issues of the synthesis and chemical characteristics of oligonucleotides and, subsequently, to introduce into the fields of their application in molecular medicine and related disciplines.

2 Oligonucleotide Synthesis

Oligonucleotides are commonly prepared by automated chemical synthesis on a solid support. For that, the nucleotide building block must contain a reactive phosphorus, allowing the formation of a 3′-5′ phosphodiester linkage. The phosphoamidite chemistry is currently the method of choice for the chemical synthesis of oligonucleotides. The phosphoamidite group contains such a reactive phosphorus linked

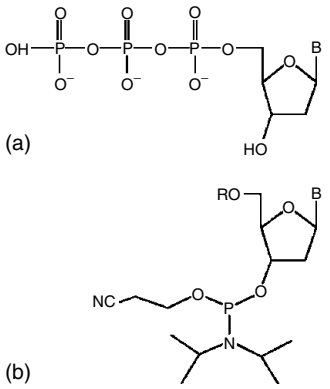

Fig. 1 Biological and chemical nucleotide monomers. (a), 2′-deoxynucleoside triphosphate as a substrate for DNA polymerases; (b), 2′-deoxynucleoside phosphoamidite as a building block for chemical oligonucleotide synthesis.

to the 3′-oxygen of the sugar moiety. This contrasts with the natural building blocks of nucleic acid synthesis, the nucleoside triphosphates, which carry the linkage-forming phosphorus on the sugar 5′-oxygen (Fig. 1). Consequently, chemical oligonucleotide synthesis proceeds in a 3′ to 5′ direction, whereas the biologic nucleic acid synthesis proceeds in the opposite direction. Other functional groups such as hydroxyl groups of the sugar and amino groups of the bases and also the phosphoamidate group itself need to be protected to exclude possible side reactions. Many companies offer oligodeoxynucleotide synthesis for very affordable prices. Oligoribonucleotide synthesis is considerably more expensive owing to more demanding synthesis protocols. The usual synthesis scales range from 10 nmol to 15 µmol corresponding to 50 µg to 10 mg of an oligonucleotide of 20 nucleotides in length. Oligonucleotide lengths of more than 100 nucleotides can be synthesized on a nucleic acid synthesizer.

An important feature of automated synthesis is the possible site-specific introduction of chemical modifications of the bases or the sugar-phosphate backbone. In conclusion, oligonucleotides can be synthesized for many different applications ranging from physicochemical over biological to medical applications.

2.1 Oligodeoxynucleotide Synthesis

The starting point of the synthesis is a protected nucleoside linked via its 3′-oxygen to a solid support (Fig. 2). Nowadays, nucleoside phosphoamidite chemistry is routinely used for this synthesis. The corresponding building blocks are shown in Fig. 2. The synthesis cycle consists of four steps: (1) Deprotection of the 5′-hydroxyl group, (2) coupling of nucleotide phosphoamidite to the 5′-hydroxyl group, (3) capping of unreacted 5′-hydroxyl groups, and (4) oxidation of the phosphorus. During the first step, the deprotection step, the DMT protection group of the 2′-deoxyribose 5′-oxygen is cleaved off to yield a free hydroxyl group. This hydroxyl group forms during the coupling step a linkage with the phosphoamidite group of the next building block, yielding a phosphite triester. The coupling step is with more than 98% of the 5′-hydroxyl groups reacting very efficient. However, there is always a small fraction of unreacted nucleosides. Since these may react during the following cycle with the next building block, leading to oligonucleotides with internal deletions, such unreacted groups are capped by acetylation. As a result, one obtains only prematurely terminated oligonucleotides but never oligonucleotides with internal deletions, which would be difficult to separate from the

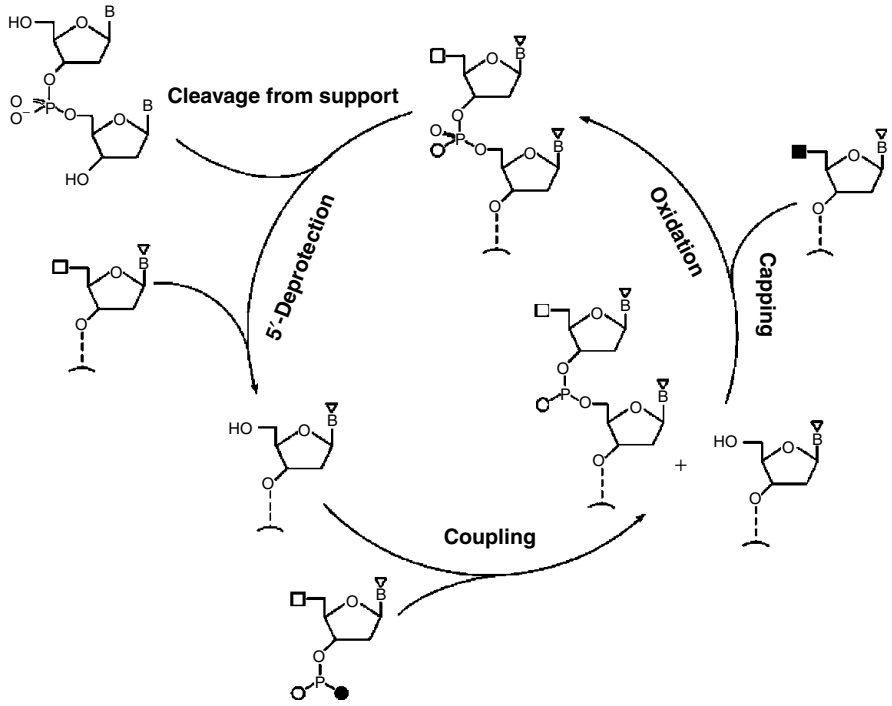

Fig. 2 Oligonucleotide synthesis scheme. The cycle for oligodeoxynucleotide synthesis is depicted. Step 1 initiates the synthesis with a nucleoside attached to a solid support and is not part of the repeating elongation cycles. B, base; white rectangle, 5′-protecting group; black rectangle, capping group; triangle, base protecting group; white circle, β-Cyanoethyl group, gray circle, amidite group. Oligoribonucleotide synthesis proceeds similarly with different building blocks containing an additional 2′-protecting group.

full-length oligonucleotide. Next, the phosphite linkage is oxidized to a phosphate linkage still carrying a protecting group at one nonbridging oxygen. The cycle is now completed; the oligonucleotide on the support is elongated by one nucleotide. After addition of the last building block, the oligonucleotide is cleaved from the solid support, and the base and phosphate protecting groups are removed. Oligonucleotides routinely contain a 5′-hydroxyl group. If a 5′-phosphate group is required, this can be introduced on the support as the final coupling step. Full-length oligonucleotides are then separated from prematurely terminated ones by either HPLC or denaturing polyacrylamide gel electrophoresis.

2.2 Oligoribonucleotide Synthesis

Like their oligodeoxynucleotide counterparts, oligoribonucleotides are synthesized using a phosphoamidite approach. The necessity of protecting the 2′-hydroxyl group of the ribose moiety results in a more demanding synthesis of the building blocks and also in a more complicated deprotection of the final oligonucleotide.

The conventional protection strategy consists of an acid-labile dimethoxytrityl

(DMT) group protecting the 5′-oxygen, and a silyl group blocking the 2′-oxygen of the ribose such as the *tert*-butyldimethylsilyl (TBDMS) or, more recently, the triisopropylsilyloxymethyl (TOM) group (Fig. 3). The TBDMS group is stable under acidic conditions and fairly stable under alkaline conditions necessary

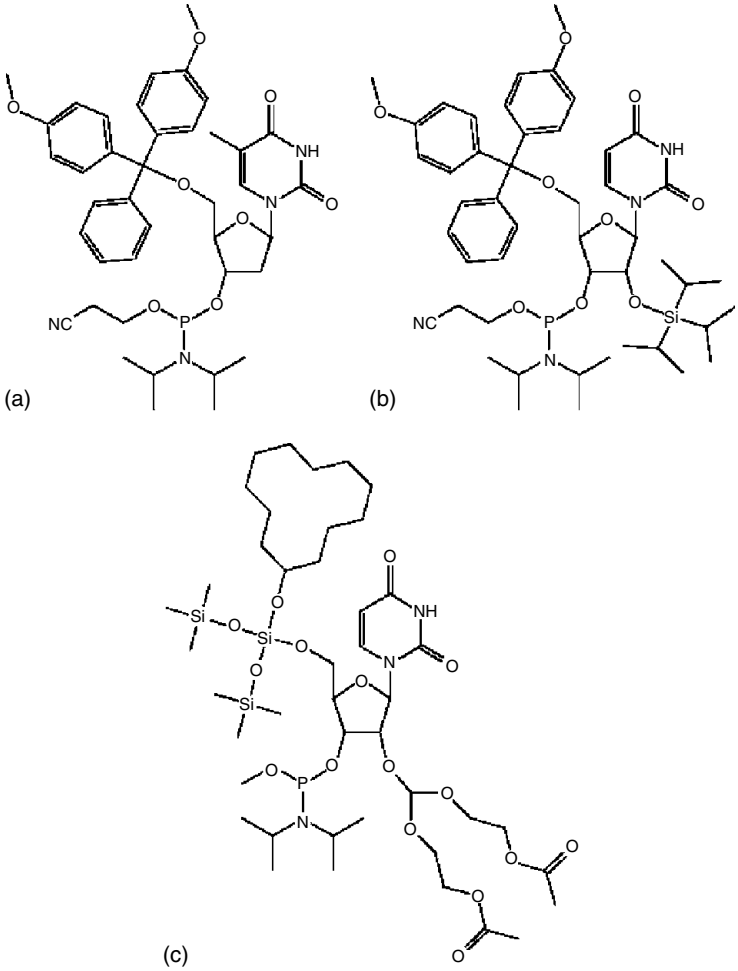

Fig. 3 Nucleoside phosphoamidite building blocks.
(a) Oligodeoxyribonucleotide building block containing a 5′-Dimethoxytrityl (DMT) protecting group and a phosphoamidite protected with a β-cyanoethyl group. (b) Oligoribonucleotide building block containing an additional 2′-O-triisopropylsilyloxymethyl (TOM) protecting group. (c) Alternative oligoribonucleotide building block containing a 2′-O-bis(2-acetoxyethoxy)methyl (ACE) protecting group, a 5′-O-Bis(trimethylsiloxy)cyclo-dodecyloxysilyl ether (DOD) protecting group for adenosine and cytidine (cyclooctyl for guanosine and uridine) and a phosphoamidite protected with methoxy group.

for the deprotection of the base functions and the phosphate linkages. However, a small fraction of the silyl groups may also be removed, resulting in strand cleavage of the oligoribonucleotide. For that reason, yields of full-length oligoribonucleotides often did not match those for oligodeoxyribonucleotides. The recent replacement of the TBDMS group by the TOM protecting group results in higher coupling yields; in combination with a modified deprotection protocol, this approach achieves full-length oligoribonucleotide yields comparable to oligodeoxyribonucleotide synthesis.

Alternatively, the 5′-oxygen can be protected by a silyl group, which can be easily removed during the synthesis cycle. In this case, an ACE group blocks the 2′-oxygen, which is stable under alkaline conditions (Fig. 3). After finishing the synthesis, cleaving the oligoribonucleotide from the solid support and deprotecting bases and phosphate linkages, the ACE group is cleaved off under mild acidic conditions. Like the previous TOM approach, this strategy achieves oligoribonucleotide yields approaching those for oligodeoxynucleotides.

Alternatively, oligoribonucleotides may be synthesized enzymatically by an *in vitro* transcription approach using DNA-dependent RNA polymerases from bacteriophages such as SP6, T3 or T7. This is still the method of choice for the synthesis of longer oligoribonucleotides. One limitation of this approach is the rather restricted set of modified nucleoside triphosphates accepted as substrates for the RNA polymerases. In addition, it is very demanding and often impossible to introduce site specifically modifications into an oligoribonucleotide.

3 Chemically Modified Oligonucleotides

3.1 Modifications of the Phosphate Linkage

The phosphate linkage is the point of attack for all nucleases. Therefore, particularly for antisense oligonucleotide applications, this linkage is a common target for stabilizing modifications.

3.1.1 Phosphorothioate Linkages

The most frequent phosphate modification is the replacement of a nonbridging oxygen by sulfur, yielding a phosphorothioate linkage (Fig. 4). This substitution creates a new chiral center in the oligonucleotide. Depending on the replaced oxygen, the phosphorothioate diester has either an Rp or an Sp configuration. Phosphorothioates are introduced during solid-phase synthesis by oxidizing the phosphite linkage with either molecular sulfur or a sulfur-transferring agent. Thus, for phosphorothioate oligonucleotide synthesis, the same phosphoamidite building blocks can be used as for the synthesis of unmodified oligonucleotides. Since the oxidation is not stereo selective, the resulting phosphorothioate oligonucleotide represents a diastereomeric mixture. In oligodeoxynucleotides, phosphorothioate groups allow for the site-specific attachment of reporter groups such as cross-linking agents of fluorescent dyes. Terminal phosphorothioates can be also introduced during chemical synthesis or afterwards by enzymatic manipulation of the purified oligonucleotide. Like internal phosphorothioate linkages, terminal phosphorothioate groups can be used for attaching dyes to the oligonucleotide. In addition, they permit coupling of oligonucleotides

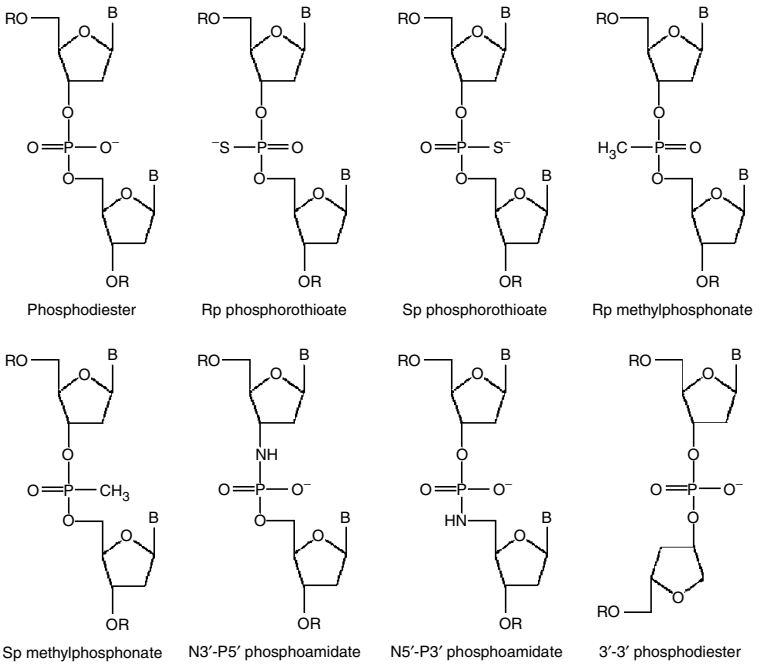

Fig. 4 Phosphate modification. Note that replacement of one nonbridging oxygen by a sulfur or a methyl group results in two different diastereomers.

to bromoacetyl agarose, for example, affinity purification of nucleic acid–binding proteins.

The phosphorothioate linkage is much less susceptible to nuclease-mediated degradation. Like unmodified oligodeoxynucleotides, phosphorothioate oligodeoxynucleotides induce RNase H-mediated degradation of complementary RNA sequences. These benefits are accompanied by some disadvantageous properties. One major disadvantage is a decreased affinity of phosphorothioate oligonucleotides for complementary sequences compared to their unmodified counterparts. Moreover, phosphorothioate oligonucleotides exhibit a strong unspecific binding to many proteins. In spite of these problems, phosphorothioate oligonucleotides are currently still the most popular antisense oligonucleotides.

3.1.2 **Methylphosphonate Linkages**

Substitution of one nonbridging oxygen by a methyl group yields a methylphosphonate linkage (Fig. 4). As in the case of phosphorothioate linkages, this replacement introduces an additional chiral center into the oligonucleotide backbone. To synthesize methylphosphonate oligodeoxynucleotides, special phosphoamidite building blocks already carrying the methyl group linked to the phosphorus are necessary. Like their phosphorothioate counterparts, methylphosphonate linkages reduce the affinity of an oligodeoxynucleotide to its complementary strand and increase its resistance against nucleases. However, methylphosphonate oligodeoxynucleotides are not as ''sticky'' as phosphorothioate oligonucleotides to proteins, and they do not support RNA degradation by RNase H.

3.1.3 **Phosphoamidate Linkages**

Phosphoamidate linkages, which should not be mixed up with the phosphoamidite building block, are characterized by nitrogen replacing either the bridging 3′- or the 5′-oxygen of the corresponding sugar part (Fig. 4). Despite their low chemical stability under acidic conditions, the 3′-*N*-phosphoamidates are particularly interesting for antisense approaches. These linkages are completely resistant against nucleases. Furthermore, in contrast to phosphorothioate or methylphosphonates, introduction of phosphoamidate linkages significantly increases the affinity to complementary nucleic acid strands. Like methylphosphonates, phosphoamidate oligonucleotides have a much lower tendency than phosphorothioate oligonucleotides to bind to proteins and do not induce degradation of complementary RNA strands by RNase H.

3.1.4 **3′-3′ Linkages**

Exonucleases degrade oligonucleotides from the 5′- or 3′-terminus. Their substrate is the 5′-3′-phosphodiester linkage. Introduction of a terminal 3′-3′-phosphodiester linkage confers resistance toward exonuclease action (Fig. 4). For instance, hammerhead ribozymes containing a 3′-terminal 3′-3′-phosphodiester linkage are efficiently protected against a 3′-exonuclease activity present in blood serum.

3.2 Sugar Modifications

3.2.1 **2′-Methoxy Oligonucleotides**

Methylation of the ribose 2′-oxygen is a naturally occurring modification found in rRNAs, tRNAs, and in the cap structure of mRNAs and snRNAs. This modification not only confers resistance to 2′-OH-dependent ribonucleases but also decreases the susceptibility toward other nucleases (Fig. 5). Since 2′-methoxyribose adopts a similar conformation as the unmodified ribose, 2′-methoxyoligonucleotides do not induce RNase H-mediated RNA degradation. However, 2′-methoxyoligonucleotide-RNA duplexes exhibit a higher thermal

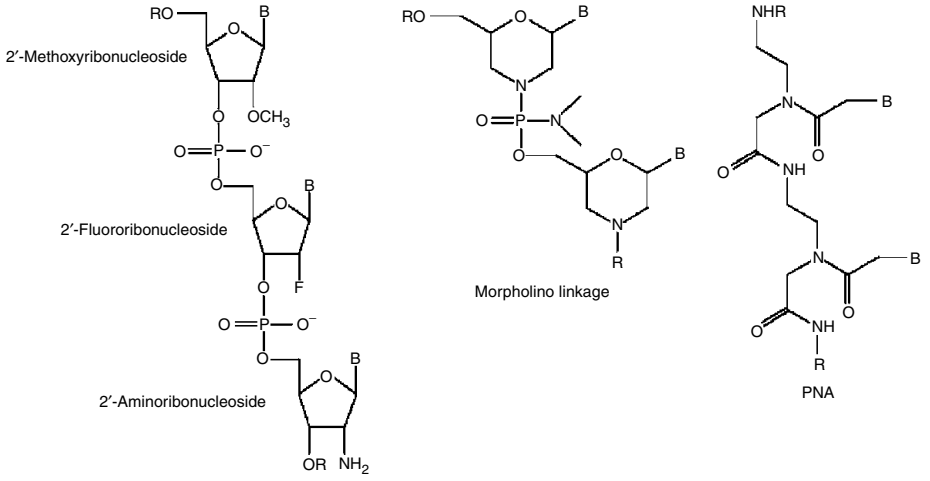

Fig. 5 Sugar and backbone modifications.

stability than oligodeoxynucleotide-RNA duplexes. 2′-Methoxyoligonucleotides are used for the isolation or depletion of RNA-binding proteins in cell lysates and for antisense applications. During the last decade, many other alkyl residues such as the methoxyethyl group or the allyl group have been introduced at the 2′-position to stabilize oligonucleotides against nuclease attack without compromising their affinity toward complementary RNA sequences.

3.2.2 2′-Fluoro and 2′-Amino Oligonucleotides

Introduction of fluorine or an amino group at the 2′-position yields 2′-fluoro or 2′-aminooligonucleotides, respectively (Fig. 5). Like the 2′-methoxy group, these modifications impart resistance toward 2′OH-dependent RNases such as RNase A. However, the affinity of oligonucleotides toward complementary RNA decreases in the order 2′-fluoro > 2′-OH (ribo) = 2′-methoxy > 2′-deoxy > 2′-amino and is paralleled by the tendency of the sugar to adopt a 3′-endo conformation. Like phosphorothioate linkages, 2′-amino groups can be used to introduce a reporter group into the sugar-phosphate backbone.

3.2.3 Morpholino Oligonucleotides

The following two examples describe modifications that replace the complete oligonucleotide sugar-phosphate backbone by new structures. The morpholino oligonucleotide contains hexameric morpholino rings and phosphodiamidate linkages (Fig. 5). The morpholino ring carries the base and replaces therefore the sugar moiety in conventional oligonucleotides. In contrast to the latter, the morpholino backbone is neutrally charged and has a lower tendency for protein binding. Such oligonucleotides are very resistant against nucleases and form duplexes with RNA of similar stability as oligodeoxynucleotides. Since such morpholino oligonucleotide-RNA duplexes are no substrate for RNase H, morpholino antisense oligonucleotides do not induce the degradation of their target RNA but block efficiently the initiation of translation when targeted against the translational start site. For that reason, morpholino antisense oligonucleotides are widely used to examine gene function in developmental model organisms such as zebra fish or Xenopus.

3.2.4 Peptide Nucleic Acids

The most radical backbone modification is its complete replacement by a peptide backbone (Fig. 5). Such peptide nucleic acids (PNAs) contain a neutral backbone and exhibit a very high affinity toward complementary nucleic acid sequences. They are completely resistant against both nuclease and proteinase-mediated decay but are less soluble in aqueous solvents than ''normal'' oligonucleotides. Unlike most other types of oligonucleotides, PNAs can invade into double-stranded DNA and may have the potential to modulate gene expression by interfering with the transcriptional process.

3.3 Base Modifications

In contrast to most modifications of the sugar-phosphate backbone, base modifications hardly affect the stability of an oligonucleotide. Instead, they often allow structure-function analyses by either substituting a functional group or by introducing new functions such as fluorescent labels or cross-linking groups. We discuss here only a small selection of base modifications amenable for automated synthesis (Fig. 6).

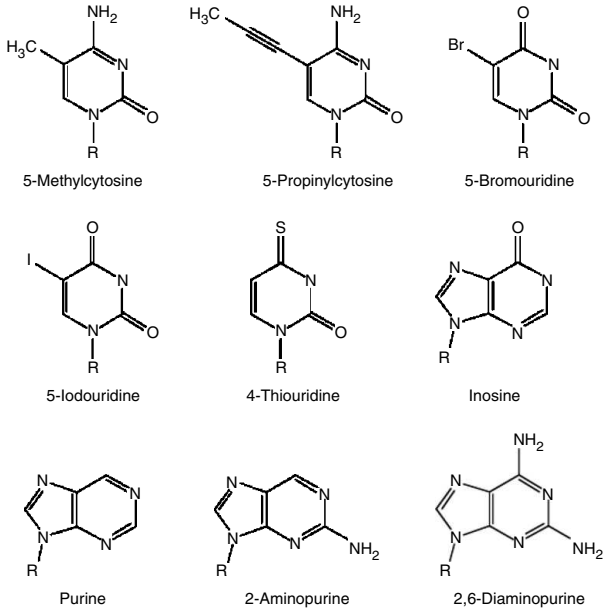

Fig. 6 Base modifications.

3.3.1 **Pyrimidine Modifications**

A prominent site for the introduction of modifications is the 5-position of the pyrimidine ring. Since this position is not involved in the formation of Watson–Crick base pairs, even quite bulky modifications can be introduced without significantly affecting the thermal stability of a nucleic acid double strand. A naturally occurring modified base is 5-methyl cytosine (Fig. 6). Oligonucleotides containing unmethylated CG motifs may stimulate immune responses, thereby negatively affecting the specificity of an antisense or an aptameric oligodeoxynucleotide. Replacement of the unmethylated cytosine by 5-methyl cytosine suppresses this immunostimulation and is thus frequently used to study such a possible mode of action. Photoaffinity labels such as 5-bromo or 5-iodo uridines can be used to crosslink an oligonucleotide to DNA- or RNA-binding proteins upon UV irradiation. In addition, cellular uptake and intracellular distribution of 5-bromo deoxyuridine-containing oligonucleotides can be examined with commercially available antibodies. Another 5-modification of the pyrimidine ring being of relevance for antisense oligonucleotides is the propinyl group. Compared to unmodified ones, oligodeoxynucleotides containing 5-propinyl cytidines and uridines show a higher affinity toward complementary RNA.

To investigate the interaction of bases with metal ions such as magnesium ions, oxygens may be replaced by sulfur. Such a replacement converts a ''hard'' center preferentially coordinating to magnesium ions to a ''soft'' center binding to calcium or cadmium but not to magnesium ions. For instance, 4-thio uridine has been applied to examine potential magnesium binding sites in the catalytic core region of the hammerhead ribozyme. Moreover, like

5-bromo uridine, 4-thio uridine is a photoactivatable cross linker to both nucleic acids and therewith interacting proteins.

3.3.2 Purine Modifications

Inosine is generated in the cell by deamination of adenosine by enzymatic adenosine deaminase activities. Inosine is frequently found in the +1 position of the tRNA anticodon loop where it can base-pair with uridine, cytosine, and adenosine. For this reason, it is used for the synthesis of primers containing degenerate base positions. Such primer can bind to DNA or RNA strands with incomplete sequence information or to a family of related sequences without a mismatch ''penalty'' reducing the thermal stability of such duplexes. Together with other modified purines such as 2,6-diamino purine or purine itself, it has been used to study protein–DNA interactions or ribozyme catalysis. The application of the fluorescent purine analogue 2-amino purine permitted the study of conformational changes associated with hammerhead ribozyme catalysis.

3.4 Nonnucleotidic Modifications

Automated oligonucleotide synthesis allows the introduction of nonnucleotidic modifications. In particular, alkyl chain groups such as the C3 or C6 chain in combination with terminal amino or sulfhydryl groups are frequently attached to the 5′- or 3′-terminus by solid-phase chemistry. After finishing the synthesis, the terminal functional group can be used to introduce further modifications or to attach the oligonucleotide to a matrix for affinity purification of, for instance, nucleic acid–binding protein complexes. In addition, carrier peptides such as antennapedia or tat peptides can be linked to the oligonucleotide via its sulfhydryl group. The resulting peptide–oligonucleotide conjugates show a significantly enhanced uptake and activity in cell culture when compared to the nonconjugated oligonucleotide alone.

Single-stranded loops are a preferred point of attack for nucleases. Replacement of such susceptible loops by an internal hexaethylene glycol linker may increase the stability of oligonucleotides hairpins in body fluids and in cell culture. For the hammerhead ribozyme, it has been shown that the replacement of its loop by such a linker hardly affected its catalytic efficiency.

3.5 Fluorescent Oligonucleotides

An important class of nonnucleotidic modifications consists of fluorochromes such as fluorescein or rhodamine dyes. Dependent on the type of phosphoamidite used, such fluorochromes can be internally as well as 5′-terminally attached. For 3′-labeled oligonucleotides, synthesis is performed on a solid support with the fluorescent dye already attached to it.

Fluorescently labeled oligonucleotides are used to study cellular oligonucleotide uptake and their intracellular distribution. Further applications are in DNA sequencing as fluorescent primers and in the analysis of intra- and intermolecular interactions by, for instance, fluorescence correlation spectroscopy. Combination of two different fluorochromes, of which the emitted light from the first dye excites the second dye, are applied in fluorescence resonance energy transfer studies. The same principle is used for real-time polymerase chain reaction (PCR), where the formation of a PCR product is followed on-line

by Fluorescence resonance energy transfer (FRET) analysis using fluorescently labeled oligodeoxynucleotide probes.

4 Applications and Perspectives

4.1 General Considerations

The application of single-stranded oligonucleotides in molecular biology is tightly related to the base-specific recognition of complementary nucleic acids usually via Watson–Crick base pairing. This means, whenever a sequence-specific detection or interaction between the oligomeric probe, tool, or drug and a nucleotide sequence of interest can be formed, this recognition step provides the signal of interest, confers specificity and selectivity, or is crucial for efficacy in biological systems. More recently, it became clear that also double-stranded RNA, including siRNA, may recognize its target RNA in a highly sequence-specific fashion, suggesting a step that involves nucleotide sequence recognition as well. Oligonucleotides represent a highly sensitive tool to qualitatively and quantitatively detect and to monitor nucleic acids in many kinds of experimental setup and environment. This includes, for example, solutions and buffers as well as structured biological material, including fixed cells and tissue slices. In the latter systems, fluorescently or radioactively labeled oligonucleotides are being used also for imaging purposes and to define the localization of specific nucleic acids within tissues, cells, subcellular structures, and compartments.

In the following, a number of such applications in molecular biology, cell biology, and molecular medicine will be described. In principle, the entity 'oligonucleotide' is the same in many fields of application in terms of length, chemistry, and biochemical function. However, the range of concepts and strategies in which oligonucleotides represent a key tool is extremely wide (Fig. 7). Here, selected key methodologies out of the large set of currently established protocols that include the use of oligonucleotides will be described in order to explain their role as a tool and drug in molecular biology.

With regard to the field of therapeutic approaches on the molecular level and the level of correction of gene expression, several classes of oligonucleotides are being used as lead compounds and as drugs in current molecular medicine. Among the potentially therapeutic oligonucleotides suited to suppress pathological and aberrant gene expression are groups such as antisense oligonucleotides, ribozymes, or double-stranded RNA as well as those inducing biological responses that are of therapeutic benefit in man, such as CpG-immunostimulatory oligonucleotides, decoys, or aptamers. To illustrate the role of oligonucleotides as drugs, some prominent groups will be discussed in chapter 5.

4.2 Applications *in vitro* and in Cell Culture

For most purposes, in biochemical reactions and for most experimental protocols commonly used in solution, *in vitro* oligonucleotides are unmodified. This means they can be obtained with little expense. However, a number of chemical modifications that improve the biochemical and biological characteristics of oligonucleotides can also be obtained from commercial suppliers at appropriate expense.

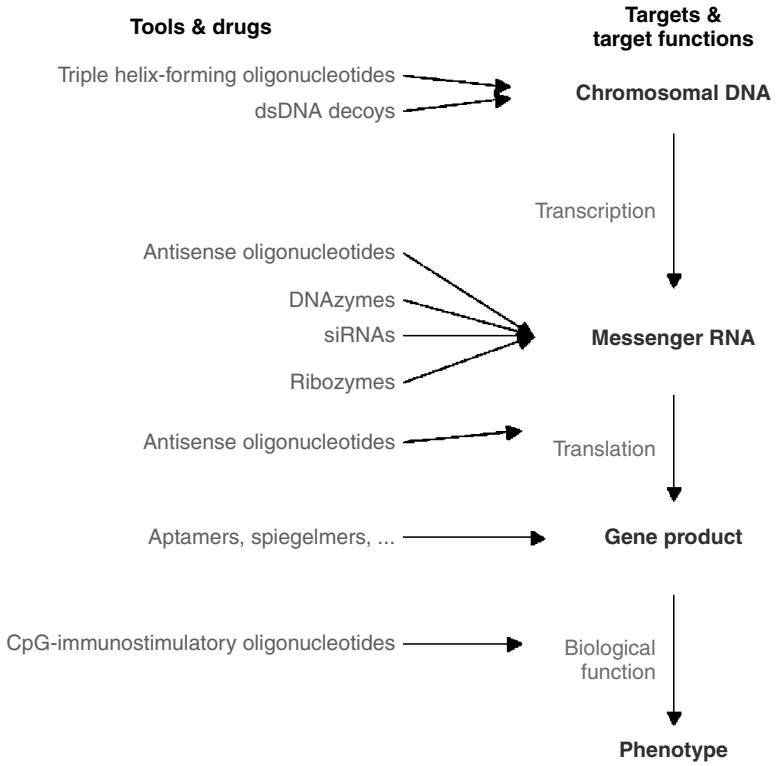

Fig. 7 Summary of modes of action of several classes of oligomeric tools and drugs acting on gene expression, gene function, and cellular processes.

4.2.1 **Primer**

In a number of extremely important and fundamental methods frequently applied in almost all fields of current biochemical, biological, and medical research, oligonucleotides serve as sequence-specific primers for enzymatic reactions *in vitro*. Such primes recognize their template in a sequence-specific manner, which confers ''specificity'' (Fig. 8). For example, oligonucleotides are commonly used as primers for directed reverse transcription of RNA into cDNA as an alternative to the unspecific oligo (dT)-primed synthesis of cDNA, or for the extension of the primer along a given template, which sheds light on position-specific characteristics of the substrate strands.

It is important to note that the binding efficiency of this step including sequence-selectivity is crucially influenced by the biochemical conditions of the reaction such as temperature, ionic conditions, and stoichiometry. A subsequent or combined enzymatic reaction usually in the use of a polymerase or domains thereof produces the signal that is used for detection or quantification of the templates that had been present in the original sample.

Primer extension reactions are also commonly used in the structural probing of RNA. In such analyses, structured RNA is modified and cleaved first in a sequence-

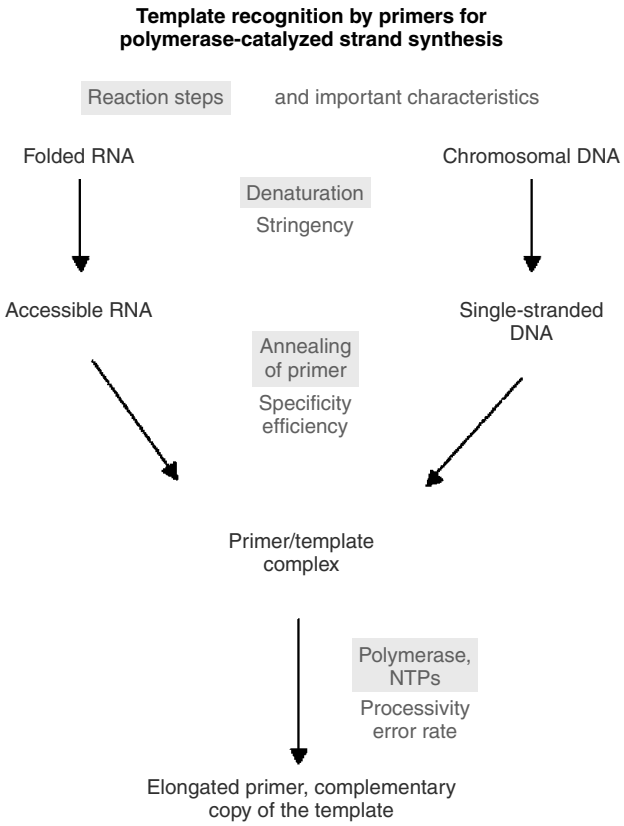

Fig. 8 Interactions between primers and their DNA or RNA templates. Key steps include the denaturation of the template and the binding of a primer to its template via base–base recognition followed by an enzymatic extension.

or structure-specific way followed by a primer extension reaction that terminates at the positions of cleavage.

Finally, and almost with an historical perspective to Sanger's work, it is worth noting that primers are crucial to the enzymatic sequence determination of DNA and RNA. Even though this kind of sequence determination is almost completely automated, oligomers as primers are still in highly frequent use.

PCR The polymerase chain reaction (PCR) makes use of two primers that direct their elongation by DNA polymerase in opposite directions such that their elongated products form two complementary single strands. They may pair to form a double-strand and increase the quantity of specific DNA double strands. However, the enzymatically synthesized double strands may also be denatured such that the primers present in excess in the reaction mixture can bind and form a new template for polymerase activity and the production of new duplexes.

At present, there are a number of academic and commercial computer

algorithms available that are held to design appropriate primers for PCR. Such programs are usually based on thermodynamic parameters and include components that align selected primer sequences with relevant sequence spaces and nontarget sequences in order to avoid the amplification of irrelevant products that give rise to false signals and results.

In situ PCR Usually, a typical PCR reaction is carried out in solution in tubes that can be heated and cooled to specific temperatures in many repetitive cycles. Such reactions can also be performed in chambers that contain fixed cells or tissues that harbor the nucleic acid of interest, which may serve as templates for PCR reactions *in situ*. The necessary nucleotide triphosphates, buffer components, and enzymes are all able to access their ''fixed'' templates inside ''fixed cells''. By incorporating chemically modified nucleotides that can be recognized, for example, by antibodies (e.g. BrdU-directed antibodies in case of incorporation of bromodeoxyuridine, BrdU) or other high-affinity molecules, the *in situ* PCR reaction products can be visualized and monitored. This technique is clearly a qualitative method and requires minimal amounts of template nucleic acids to be detected. For example, in case of the detection of viral nucleic acids in infected cells and tissues, this method is very helpful to investigate the time course and subcellular localization of genomic and subgenomic viral nucleic acids.

4.3 Probes

In order to detect nucleic acids of interest, one usually exploits the specificity of Watson–Crick hydrogen bonding between two complementary strands. The strand to be detected can be recognized by a complementary oligonucleotide that contains a detectable label, for example, a radioisotope, a fluorescent moiety, or a substituent, which can be labeled subsequent to double-strand formation such as biotin or BrdU. Probes of oligomeric length offer certain advantages and disadvantages. The possibility to chemically synthesize oligonucleotides provides some of the most obvious advantages. Probes can be chemically modified such that they have improved properties, including increased binding stability (e.g. PNA, 2′-alkyl derivatives), increased resistance to nucleases usually present in biological environments (e.g. α-anomeric DNA, 2′-fluoro, 2′-alkyl), or improved discrimination between perfectly matching substrate strands and not perfectly matching strands.

In order to image nucleic acids and certain nucleotide sequence segments within chromosomal DNA, chemically modified and fluorescently labeled oligomeric nucleic acids are important. For example, 2′-*O*-allyl-modified riboprobes carrying a fluorescent label had been successfully used to determine the subcellular localization of small RNAs by image analysis of cells fixed *in situ*. And probably even more importantly, fluorescently labeled probes can be used for ''fluorescence *in situ* hybridization'' (FISH), a method routinely used to detect chromosomal aberrations in a diagnostic fashion.

4.4 Tools: Gene Function Analysis – Gene Validation

Oligomeric nucleic acids comprise a large set of functionally distinct subgroups of oligonucleotides. Prominent classes of oligomeric tools and drugs used in molecular biology include (i) short

double-stranded RNA most commonly termed ''siRNA'', micro RNA or ''miRNA'', (ii) antisense oligonucleotides, (iii) triple helix-forming oligonucleotides, (iv) catalytic RNA and catalytic DNA (DNAzymes), (v) immunostimulatory CpG-oligonucleotides, and (vi) aptamers. It seems to turn out that other subgroups of potential oligomeric drugs such as spiegelmers, intramers, or aptazymes are not equally established yet.

Predominantly antisense oligonucleotides, siRNA, and ribozymes are well suited to suppress the expression of specific genes in target cells and tissues of interest, thereby giving rise to knockdown and even knockout phenotypes of treated cells with respect to the expression of the target gene. This represents a crucial step in complex approaches to study the biological function of unknown genes, probably one of the major bottlenecks of research in the postgenome area. However, knowledge on the biological role of genes identified in genomewide mapping of genetic information is also crucial to the identification of new drug targets and the search for new drugs.

5
Applications *in vivo* and in Man (''Drugs'')

5.1
Suppression of Pathological Gene Expression

A number of nucleic acid inhibitors are capable of suppressing gene expression at the posttranscriptional level in mammalian cells, including antisense nucleic acids, siRNA, and catalytic RNA. Those nucleic acids can be subdivided into at least two categories according to their mode of synthesis and delivery: oligomeric and usually synthetic ones on the one hand and long-chain molecules usually expressed endogenously after transfer of recombinant genes into target cells on the other hand. In the latter case, viral or nonviral vectors systems have to be used to deliver the therapeutic gene of interest into target cells *in vivo*. This mode of the application of recombinant genes encoding antisense RNA, siRNA, or ribozymes has to be assigned to the field of gene therapy. Recent drawbacks in this field of biomedical experimental therapy in man revealed the complexity of this kind of therapeutic concepts. Conversely, chemically synthesized oligonucleotides can be regarded as quasi-classical drugs for which there are clear schemes to test their toxicity and relevant pharmacological characteristics before delivering to patients along established lines. Thus, it is not surprising that in the field of antisense nucleic acids, by far the most clinical studies are being conducted in the use of antisense oligonucleotides.

5.2
Antisense Oligonucleotides

In general, the most frequently used chemistry for almost all classes of oligonucleotides that are used as a drug in clinical studies in man, in particular, antisense oligonucleotides, is the phosphorothioate chemistry. Even though this sort of first-generation chemistry has been substantially improved in terms of biochemical and biological parameters *in vitro* by second- and third-generation chemistry, it remains by far the most frequently used chemistry in the most advanced clinical studies. Accumulated experience from more than one decade of *in vivo* studies in the use of phosphorothioate-modified oligonucleotides revealed that side effects are mild and usually typical

for the sulfur modifications rather than specific sequences used. For this reason, it seems that this kind of chemistry will also be used for *in vivo* application in the near future.

In the beginning of clinical studies in the use of antisense oligonucleotides more than one decade ago, one usually addressed severe diseases such as, for example, cancer, chronic inflammation, or infection by highly pathogenic viruses. Most of such clinical trials were not successful and were terminated. If one can learn from those failures, then probably two major messages are important to note: Firstly, in technical terms it seems to be disadvantageous to deliver oligonucleotides systemically *in vivo*. This means that relatively high absolute doses have to be applied in order to achieve the necessary minimal concentrations at the site or tissue of action. This is expensive and for most cell types and tissues also inefficient. Secondly, if one aims to apply antisense oligonucleotides for therapeutic purposes, that is, to suppress the expression of a specific gene that is assumed to play a crucial role for the development of a specific disease, the pathomechanism has to be known. In case of cancer and other complex diseases, this is often not sufficiently the case. Choosing an inappropriate target or not all necessary targets that are related to the pathomechanism underlying a certain disease retrospectively often explains the lack of clinical success.

To avoid technical problems such as those mentioned above, one increasingly changes the way of the delivery of therapeutic oligonucleotides. For example, efficient body distribution and pharmacokinetics can be achieved by delivering formulated antisense oligonucleotides to the skin of patients from which the oligonucleotides are taken up and distributed systemically. Alternatively, local and topical application of antisense oligonucleotides represents a promising mode of delivery since amounts of the drug are minimal, and local concentrations are high.

In perspective to the near and midterm future, it is reasonable to assume that antisense oligonucleotides will remain the major class of inhibitors for drug development. In particular, some of the ''second generation'' chemistries of oligonucleotides showed very promising activity in cell culture and animal models, indicating the competitive characteristics of antisense drugs versus other classes of oligomeric nucleic acid drugs such as catalytic RNA and DNA and even double-stranded RNA.

5.3 Ribozymes

Initially, that is, more than 10 years ago, the concept of using ribozymes as tools to specifically recognize and hydrolyze a given target RNA and, hence, to suppress the expression of a specific gene was considered as highly elegant and promising. It turned out, however, that a number of criteria were not in favor of the clinical application of this class of potential drugs, including the costs of production and purification, the somewhat moderate biological activity *in vivo* when compared with antisense oligonucleotides, and more promising alternative concepts to deliver ribozymes almost in the field of somatic gene therapy. For example, the endogenous expression of ribozymes after transfer of recombinant genes expressing specific ribozymes cassettes in relevant tissues and cells seems to be promising.

5.4 Small RNAs – siRNA

Currently small RNAs that are formed by two short strands such as conventional siRNA or just a single RNA molecule forming ''hairpin siRNA'', snRNA, snoRNA, or miRNA represent the most promising class of potential oligonucleotide drugs. In principle, those RNAs can be synthesized by chemical means as well as endogenously by intracellular expression from appropriate templates to be delivered to target cells. In contrast to the application of chemically synthesized catalytic RNA meanwhile, a number of elegant concepts for the endogenous expression have been shown to be effective and to give rise to substantial biological effects.

On a more general level, one has to note that the specificity of such RNA compounds is still under question as the literature describes side effects such as induction of interferon or cosuppression of nontargeted genes controversially.

5.5 CpG-Immunostimulatory Oligonucleotides

Oligonucleotides harboring a 5′-CG-3′ dinucleotide termed *CpG* motif can exert immunostimulatory effects on subsets of immune cells in mammals, which are thought to support and even induce processes that are of therapeutic benefit in case of certain diseases such as cancer. It is attractive to assume that the concentration of CpG-carrying oligonucleotides necessary to induce significant biological effects *in vivo* is relatively low. Side effects seem to be negligible at those applied concentrations, and clinical studies in the use of CpG-immunostimulatory oligonucleotides are promising.

A number of other classes of oligomeric tools and drugs are known. For those, ''proof of principle'' has been shown *in vitro* or in cell culture; however, it seems that most of them do not play a major role in clinical drug development, which is the major field of interest in biomedicine and molecular medicine. Those classes include the above-mentioned aptamers, intramers, as well as the nuclease-resistant spiegelmers that are also developed as aptamer-like molecules. Further, within the context of diagnostic medicine, it is warranted to mention the imaging of proliferating tissues in man using radiolabeled pharmaceuticals (PET). The attempt to use oligonucleotides in PET is meant to provide a highly sequence-specific step in order to distinguish between malignant and nonmalignant cells.

6 Prospects

Oligonucleotides as drugs and tools in molecular medicine look back to approximately 25 years of research and development. The field of antisense nucleic acids and catalytic RNA has pioneered the application of oligonucleotides as pharmaceuticals. Later, CpG-immunostimulatory oligonucleotides have added to the clinical development of oligonucleotides. In the late 1990s, however, the field of oligomeric nucleic acids seemed to become less dynamic until the discovery of small double- and single-stranded RNAs that exert high biological activity and to represent a powerful class of regulators on the level of gene expression. With the characterization of siRNA and the various groups of small noncoding RNAs preferentially, oligoribonucleotides (RNA) moved into the focus of biomedical research, and it is not

difficult to predict that the field of ''oligonucleotides'' will have a great benefit and support by those recent findings.

Keywords

Oncogene
Broadly defined, an oncogene may be considered a cellular or viral gene whose product in altered form and/or greater amount can cause malignant transformation. Oncogenes function in a dominant manner because they can transform cells despite expression of their normal counterparts. The classical oncogenes are more strictly

defined by functional analysis, that is, a gene that when introduced into a cell, typically NIH3T3 cells, can transform the cell with some attributes of malignancy. More recently, it has been shown that a combination of oncogenes (e.g. RAS family and MYC family) are required to induce one or more characteristics of neoplastic transformation when introduced into ''truly normal'' cells, such as primary mouse embryo fibroblasts (MEFs).

Oncoproteins
Oncoproteins are the protein products encoded by oncogenes.

Proto-oncogene
Proto-oncogenes are normal cellular genes that can be converted to active oncogenes.

Tumor suppressor gene
Tumor suppressors are those genes that encode for proteins that prevent normal cells from becoming cancer cells, and when their functions are lost, contribute to the genesis of cancer.

Oncogenes are cellular or viral genes whose products in altered form and/or greater amount can cause malignant transformation. The hallmarks of cancer cells include loss of control of cell growth and proliferation, loss of control of cell survival and apoptosis, metastasis, and gain of immortality. Oncoproteins, the protein products encoded by oncogenes, could disrupt the normal regulation of these processes at many levels in cell signaling and gene expression. Oncogenes could be divided into these major categories: growth factors and extracellular mitogenic signals, cell surface receptors, proteins associated with inner surface of the plasma membrane, cytoplasmic proteins in various signaling pathways, proteins associated with mitochondria, nuclear proteins, and transcription factors. Instead of being caused by a single gene, malignant transformation from a normal cell to cancer cell is the end-point phenomenon resulting from accumulated genetic and epigenetic alterations. The appropriate combinations or order of altered oncogenes and tumor suppressors are required for different stages of tumor progression. Clinically, oncogenes are important diagnosis biomarkers and therapy targets for cancer.

1 Introduction

Cancer cells arise as a result of a process known as malignant transformation. Over the course of a normal cell's life span, it might acquire multiple genetic and epigenetic changes. Some of these changes are directly related to malignant transformation, while most are not. However, in the rare cell in which the combination of changes and environmental conditions are just right, that once normal cell can become cancerous, displaying

phenotypic characteristics, which include loss of control of cell growth and proliferation, loss of control of cell survival and apoptosis, and metastasis (Fig. 1). In the human body, a variety of different kinds of cells constitute different tissues and organs, and these cells are maintained at homeostasis and restricted at the proper positions of the tissues or organs. The human genome is composed of about 2.9 billion nucleotide base pairs and about 30 000 to 40 000 protein encoding gene loci, cells of a particular cell type display a certain profile of expressed genes to fulfill their physiological functions as well as to regulate cell growth, proliferation, senescence, and apoptosis. Oncogenes and tumorsuppressor genes encode for two families of proteins that, when aberrantly expressed, are thought to contribute greatly to cancer. Tumorigenesis is a complex multistep process, including tumor initiation, tumor progression to form tumor mass (escape of many constraints), and metastasis. In addition to the conversion of a normal cell to tumor cell, changes in substratum, angiogenesis, escape from immune surveillance, metastatic spread, and seeding and survival in the secondary tumor sites are all critical steps for tumor cells to escape the normal regulations and become malignant. In this review, we will focus on the oncogenic genes in the cellular transformation process. First we will discuss oncogenes and molecular mechanism of cancer, followed by a description of the biochemical properties and cellular functions of several well-studied oncogenes. Then we will discuss identification of oncogenes, followed by the clinical implication of oncogenes in cancer diagnosis, prognosis, and therapy.

2 Oncogenes and Molecular Mechanism of Cancer

2.1 Historical Perspective of Oncogenes

Malignant transformation from a normal cell to cancer cell is the end-point phenomenon resulting from accumulated genetic and epigenetic alterations in the cell. The belief that genetic damage might be responsible for cancer arose from a variety of sources: the recognition of hereditary predisposition to cancer, the presence of damaged chromosomes in at least some cancer cells, the connection between susceptibility to cancer and impaired ability of cells to repair damaged DNA, and

Fig. 1 Malignant transformation from a normal cell to become cancer cells and formation of tumor mass. In normal tissue or organ, any particular cell type is maintained in the range of a certain number to maintain tissue homeostasis. A normal cell becomes a cancer cell when the cell contains dysfunctional oncogene(s), tumor suppressor gene(s), and those involved in telomere maintenance. Cancer cells display phenotypes of loss of control in cell growth and proliferation, loss of control in cell survival, or loss of control of cell senescence, and gain of immortality. Senescent cells or cells with gene mutation(s) are monitored by the cellular intrinsic checking programs and also by the body systemic immune surveillance mechanisms, and will be cleared in most cases by these mechanisms. Only under the circumstances that the cancer cell escapes these surveillance mechanisms will the cell continue to proliferate to form tumor mass (primary tumor) in the body. This could be a very long process, sometimes in decades. With time, other genetic mutations accumulate in the cancer cells and some of them gain the potential for metastasis.

evidence that relates the mutagenic potential of substance to their carcinogenicity. Nowadays we know that the vast majority of human cancers are caused by genetic or epigenetic changes in the genome of the cancer cells and only a very small fraction of cancer cases, such as cervical and liver, may be attributed to viral infection. However, the work on retroviruses in the earlier days of cancer research did open the door for the discovery of oncogenes. The first identified oncogene, *Src,* discovered in 1976 by the Nobel Laureate Harold Vamus and J. Michael Bishop, is the archetype of those viral oncogenes. It had been known since 1909 that Rous sarcoma virus (RSV) infection of chicken cells lead to tumors, but the *v-Src* gene as the cause of the malignant transformation was not identified until the 1970s. Studies by Varmus and Bishop further demonstrated that the *Src* gene was originally a cellular gene instead of a viral gene, but was picked up and integrated into the viral genome by an ancestor of the RSV (Fig. 2). Normal cellular genes that can be converted to active oncogenes are therefore referred to as proto-oncogenes. Other such viral oncogenes include *MYC* (avian myelocytomatosis virus), *RAS* (rat sarcoma virus), *ERBB1* (avian erythroblastosis virus), *ABL* (Abelson murine leukemia virus), as well as others.

In addition to virus-mediated proto-oncogene activation, many other mechanisms have been identified in cancer cells that can lead to activation of proto-oncogenes. At the genetic level, each gene

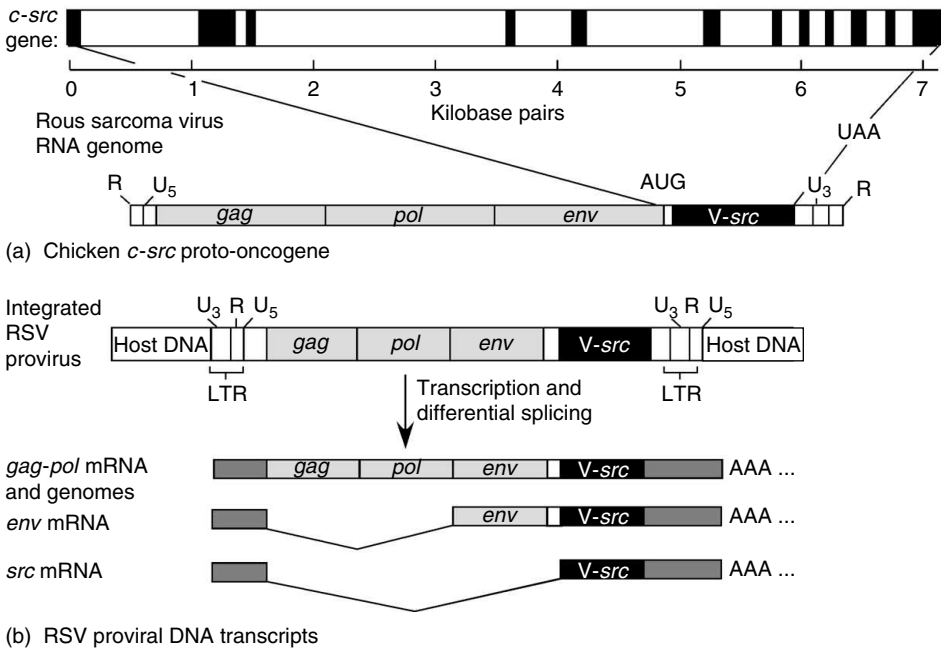

Fig. 2 The *c-SRC* proto-oncogene and the *v-SRC* oncogene. The cellular proto-oncogene *c-SRC* was picked up and integrated into the RSV genome as *v-SRC* (a), which encodes the v-SRC oncoprotein responsible for the malignant transformation of RSV (b).

has to be transcribed at the appropriate level within a certain time frame, and then translated into a functioning protein. Normally, the proto-oncogenes are latent or strictly regulated to perform their normal physiological functions in the cell life. The mechanisms involved in abnormal activation of proto-oncogenes include the following: virus-mediated, chromosome translocation, gene amplification, small deletions or insertions, point mutations, and aberrant gene expression caused by epigenetic alterations such as DNA methylation and histone deacetylation. In some cases, the activity of oncoproteins may be increased by other proteins regulating their stability or degradation. An example is that HSP 90 (heat-shock protein 90) may increase the stability of several oncoproteins such as HER-2, AKT, and KIT.

While many genes might be found altered in cancer cells and most of them are not related to malignancy, the alterations in oncogenes and tumor suppressor genes are most directly responsible for malignant transformation. The number of oncogenes and tumor suppressors identified to date is controversial and is dependent on the rigor of the definition. The classical oncogenes are usually defined by functional analysis, that is, an oncogene is a gene that when introduced into the cell can transform the cell with some attributes of malignancy. With the better understanding of the molecular mechanism of tumorigenesis, we know that the effect of a particular oncogene is dependent on the cellular context. In most cases of tumors, alterations in other oncogenes or tumor suppressor genes are required for a particular oncogene to exert its role in tumor pathogenesis. Therefore, an oncogene will be defined as a cellular or viral gene in its wild type or mutant form that can induce one or more characteristics of neoplastic transformation when introduced, either alone or in combination with another gene, into an appropriate cell type. Oncogenes function in a dominant manner because they transform cells despite expression of their normal counterparts. However, there are examples in which inherited mutations in oncogenes such as KIT, RET, and MET can predispose to cancer. In broad terms, tumor suppressors are those genes that encode for proteins that prevent normal cells from becoming cancer cells, and the loss of their functions contributes to the genesis of cancer.

2.2 Molecular Mechanisms of Cancer

There are two major features of cancer cells: one is the loss of control of cell growth and proliferation, resulting in loss of homeostasis and formation of tumor mass and the other is metastasis for tumor cells to migrate away from their normal location and invade into another tissue or organ. To maintain tissue homeostasis, a normal cell is strictly regulated for cell differentiation, cell growth and proliferation, cell survival and apoptosis, and cell senescence. Deregulation of proto-oncogenes and tumor suppressor genes might contribute to tumorigenesis by disrupting one or more of these processes (Fig. 1). In the process of tumorigenesis, cancer cells can acquire metastatic potential, that is, they migrate into the blood or lymphatic circulatory systems, circulate in the peripheral blood and arrest in a distant organ, extravasate from the vessels, dwell in the distant organ and form tumor masses. Oncogenes may promote metastasis by enhancing cancer cell motility and invasion, and by

promoting cancer cell survival and inhibiting apoptosis under adverse conditions in the process of metastasis. Changes in the environment such as extracellular matrix and angiogenesis are involved in the formation of primary tumors as well as the metastases; oncogenes are also involved directly or indirectly in these processes.

Cell growth and proliferation are regulated through cell cycles, and oncogenes could be derived from those proto-oncogenes that promote cell cycle progression or those that release the inhibitory functions of the negative regulatory molecules of cell cycle. The cell cycle for somatic cell division can be divided into four phases: the G_1 gap phase for preparation of DNA synthesis, the S-phase for DNA replication, the G_2 gap phase for preparation of mitosis, and the M-phase for separation of daughter chromosomes and completion of one cell cycle. The key proteins involved in cell cycle progression are highly conserved among different cell types in higher eukaryocytes, these include cyclins, CDKs (cyclin dependent kinases), CKIs (CDK inhibitors), RB (retinoblastoma protein), and the transcription factor E2F (E1A-inducible factor) (Fig. 3). CDKs are the engine proteins driving cell cycle progression, with CDKs-4, -6, and -2 working in G_1-phase, CDK2 working in S-phase, and CDK1 (CDC2) in G_2- and M-phases. Activation of the CDKs is positively regulated by cyclin binding, and synthesis of cyclins is strictly regulated during different phases of the cell cycle. G_0 and G_1 phases are the interface for the interaction between cell cycle machinery and the extracellular signals, including both mitogenic and inhibitory signals, cues from extracellular matrix, and cell–cell interactions. D-type cyclins are very unstable proteins with very short half-life, and their production is controlled at transcriptional level and regulated by mitogenic signaling. For example, cyclin D1 promoter contains binding sites for AP1, ER-E2/X, SRE, E2F4, E2F1, SP1, CRE, MAPK-c-ETS2-ETS. Synthesis of D-type cyclins awakes quiescent cells (G_0) to enter the G_1-phase of the cell cycle. In late G_1-phase of the cell cycle, there is a restriction point and continued mitogenic stimuli are required for the cycling cells to pass this point (Fig. 3). Once beyond this point, cell cycle progression becomes autonomous and cell cycle will be completed to give two daughter cells unless stalled by the checkpoint mechanisms. The main target of CDKs is the retinoblastoma protein encoded by tumor suppressor gene *RB*. In quiescent (G_0) cells, RB is hypophosphorylated and binds to E2F. The activated CDK4/6 then phosphorylates RB, resulting in dissociation of E2Fs from RB. E2Fs are transcription factors and their target genes include those essential for DNA synthesis in S-phase as well as cyclins (D, E, and A). Cyclins D and E activate CDK4/6 and CDK2 respectively, which further promote G_1-phase progression to pass the Restriction point. Cyclin A activates CDK2 to promote S-phase progression, and G_2- and M-phases are promoted by cyclin B/CDK1 and cyclin A/CDK1 respectively. Cyclin E/CDK2 peaks at the G_1–S transition, and is thought to help the cell transverse the restriction point. Cyclin E is rapidly degraded in S-phase, and cyclin A binds to CDK2 in S-phase for S–M phase transition.

Derangement of cell survival and apoptosis is another important feature contributing to tumor mass formation and tumor progression. Damaged or senescent cells and cells receiving death signals from the environment must be cleared to maintain the normal function and normal

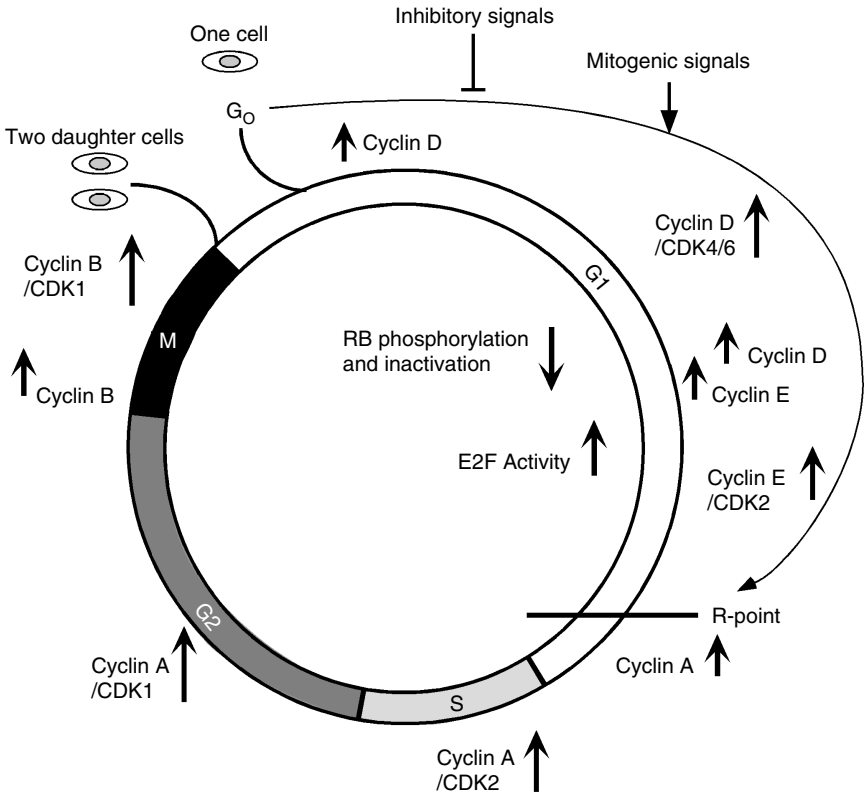

Fig. 3 Cell cycle and the key regulatory molecules. In somatic mitotic cell division, one cell produces two daughter cells after each cell cycle. Most of the differentiated cells in the body are in quiescent state (G_0), and they enter the cell cycle under the stimulation of mitogenic signals such as growth factors. The cell cycle is driven by the CDKs with different CDKs acting in different phases of the cell cycle, and CDKs are activated by cyclins. The target genes of E2F and the target genes regulated by cell signaling cascades initiated by the mitogenic signals are required for the progression in G_1-phase. Once beyond the R-point (restriction point) in late G_1-phase, cell cycle progression becomes autonomous, and no further mitogenic signals are required. E2F is negatively regulated by RB, and RB can be inactivated by CDK-mediated phosphorylation.

life span of a cell, and various oncogenes are known to block the execution of cell death pathways and/or activate the cell survival pathways to promote tumorigenicity (Fig. 1). There are two major pathways for the initiation of apoptosis, one is initiated from the death receptors (such as FAS and TNF receptors) on the plasma membrane and is largely independent of mitochondria; the other is mitochondria-mediated apoptotic pathway initiated by environmental stress signals or by DNA damage signals from the nucleus (Fig. 4). Under certain circumstances, mitochondria might also be involved in death receptor–mediated apoptotic pathway. Caspase-8 is the initiator caspase activated by death receptor, while caspase-9 is the initiator caspase activated by cytochrome C released from mitochondria.

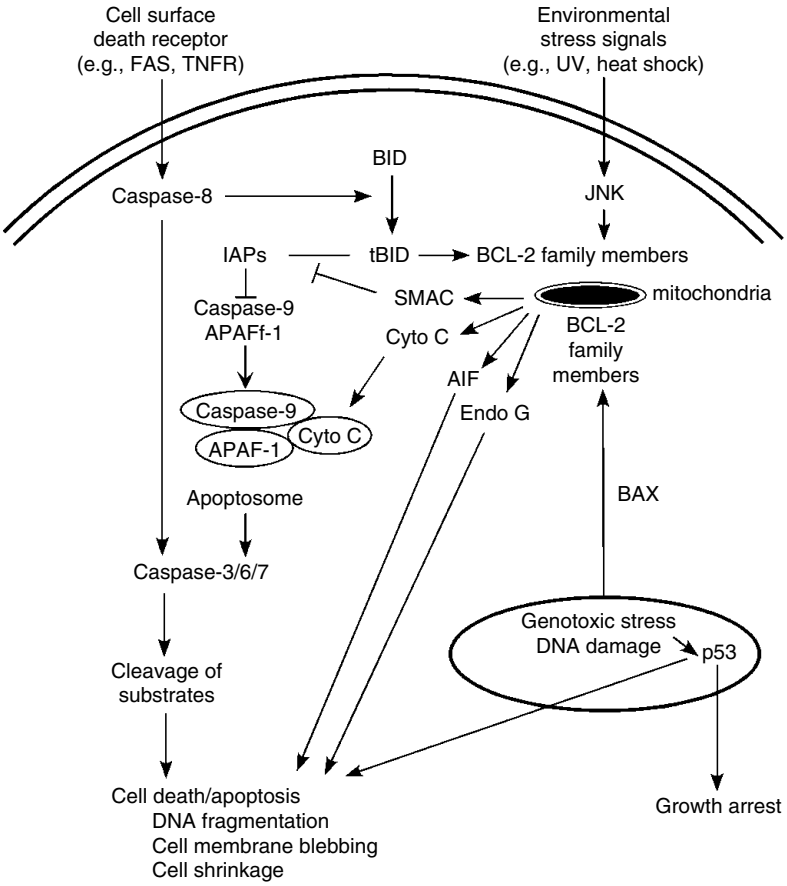

Fig. 4 Regulation of cell apoptosis. There are two major cellular apoptotic pathways, one is initiated from the cell surface in response to activation of the cell surface death receptor(s), and the other is mediated by dysfunctional mitochondria as a response to stress stimulations or nuclear chromatin DNA damage. In both pathways, caspases are involved, and the effector caspases for both pathways are caspases-3, -6, and -7. Many cytoplasmic and nuclear proteins are the substrates of the effector caspases, and cleavage of these substrates leads to apoptosis with cell membrane blebbing, cell shrinkage, nuclear chromatin DNA fragmentation, and so on.

The two pathways merge at the effector caspases-3, -6, and -7. Protein cleavage by effector caspases eventually leads to apoptosis, including cell membrane blebbing, chromosome DNA fragmentation, and cell shrinkage. In mitochondria-mediated apoptotic pathway, the BCL-2 (B-cell lymphoma/leukemia-2) family members play the critical role as gatekeeper in regulating the release of cytochrome C, SMAC (the second mitochondria-derived activator of caspase), and HTRA2 (high-temperature requirement factor). Cytochrome C together with APAF-1 bind to caspase-9 to form apoptosome, leading to activation of caspase-9, and SMAC

and HTRA2 bind IAPs and release their inhibition on effector caspases.

In the progression of tumorigenicity, cancer cells also acquire cell immortality. For differentiated somatic cells, the number or times a cell can proliferate is extremely limited because the length of telomere becomes shorter after each cell division, and eventually the telomere will become too short to permit further cell division. For cancer cells to continue to proliferate and form tumor mass or metastasis, some mechanism has to be adapted to overcome telomere shortening during each cell cycle. The mechanisms involved in telomere maintenance could be mediated either by increased telomerase activity, or by a process referred to as *alternative lengthening of telomeres* (ALT).

2.3 Models of Molecular Oncogenesis: the Two-hit Hypothesis and Multistep Tumorigenesis

One of the earliest models regarding molecular oncogenesis is the ''two-hit hypothesis'' proposed by Knudson on the basis of their studies of hereditary cancer. According to this model, for a cell carrying a germline mutation in one allele of tumor suppressor gene (the first hit) to become a cancer cell, the cell needs to acquire a second hit (somatic mutation in the remaining wild-type allele). This hypothesis led to the cloning of the first tumor suppressor gene, *RB*. Today we have a much better understanding of tumorigenesis; however, the two-hit hypothesis is still valid, although it is continually modified to reflect new knowledge. For example, it is clear that multiple genetic and epigenetic alterations must take place to cause a cell to become cancerous. Therefore, we can think in broader terms and consider the activation of an oncogene as the first hit, and the loss of tumor suppressor activity as the second hit, or vice versa. In addition to oncogenes and tumor suppressor genes, the telomere maintenance mechanism is required for the formation of tumor mass and might represent a distinct kind of hit on oncogenes.

As indicated above, tumorigenesis is a very complicated process consisting of multiple steps, including tumor initiation, tumor progression, and metastasis. The hit on different oncogenes or tumor suppressor genes might be required at different steps as exemplified in colon cancer (Fig. 5). The initiation and early stage of tumor progression is very slow, sometimes it takes years or decades for a malignant cell to form noticeable tumor mass (i.e. 1 cm diameter, or 1000 million cells). One major reason is that not all cells with active oncogene(s) will become cancerous, and not all cancer cells will escape the various surveillance mechanisms within the cell and in the body and survive to form tumor mass. In most carcinomas, cancer is not a disease caused by a single gene. It is more like a syndrome; within the cancer cells, the appropriate combinations or order of altered genes are required for different stages of tumor progression (Fig. 5), and, within the body, the immune surveillance needs to be either defective or compromised. For example, loss of *APC* (adenomatous polyposis coli) gene function is required for tumor initiation, while mutation of *RAS* alone or *p53* alone is not sufficient for tumor initiation, although both are required for tumor progression. For most, if not all, important cellular processes, the cell is regulated by the balance between positive and negative regulatory mechanisms at multiple levels. Therefore, the same kind of hit might occur at different steps of

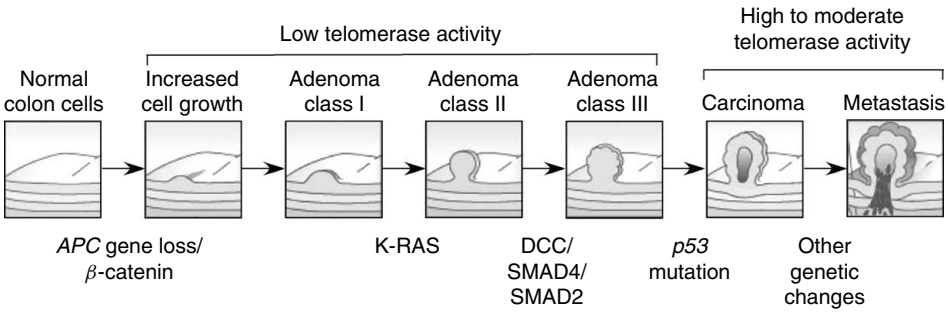

Fig. 5 Model of tumorigenesis: multistep carcinogenesis and the two-hit hypothesis. Colon cancer progression is a multistep process, involved with tumor initiation, tumor progression, and metastasis. The *K-RAS* oncogene and several tumor suppressor genes including *APC* and *p53* are involved in different stages of tumor progression. In tumor progression and metastasis, increased telomerase activity is involved in the maintenance of telomeres of the cancer cells.

tumorigenesis. For oncogenic transformation, the right combination of two or more oncogenes, such as *RAS* and *MYC*, might be considered as one kind of hit at different levels. In addition to RAS, telomerase activity is also a requirement for tumor progression and metastasis in colon cancer. While telomerase activity is not detectable in normal colon tissue, telomerase activity is low in polyps or adenomas and high to moderate in carcinomas and metastasis. For tumor suppressor genes, the serial loss of tumor suppressor genes *APC* and *p53* in hereditary colon cancer might be considered as another kind of hit at different stages of tumorigenesis. A similar situation is also found in lung cancer, that is, multiple oncogenes and tumor suppressor genes are involved. Finally, the kind of hit in some cases might function as a different hit in other circumstances, and some genes might be involved in more than one kind of hit. For example, MYC could act as either an oncogene to promote cell proliferation or a tumor suppressor to sense cells to apoptosis, depending on the particular circumstances, and the tumor suppressor gene p53 might also be involved in telomere maintenance (an event considered as oncogenic).

2.4 Major Categories of Oncogenes

Oncogenes can be classified into different categories based on different criteria. According to their origin, oncogenes could be divided into viral oncogenes and cellular oncogenes. Oncogenic viruses fall into two categories, the DNA viruses and retroviruses. As described above (see Sec. 2.1), retroviral oncogenes were originally derived from cellular proto-oncogenes. The oncogenic DNA viral oncogenes include Simian virus 40 (SV40) large T-antigen, polyomavirus middle T- and large T- antigens, papillomavirus E6 and E7 proteins, adenoviruses E1A and E1B proteins, herpesviruses such as Epstein Barr virus (EBV) LMP1 and other viral proteins, hepatitis B virus (HBV) X gene-encoded protein.

Cellular oncogenes can be further divided into different categories based on their subcellular locations, protein

structures, and their functions in cellular physiological processes. In this review, we will integrate these criteria and divide the oncogenes into these major categories: (1) Oncogenes in cell cycle progression and cell division; (2) growth factors and extracellular mitogenic signals; (3) oncogenic cell surface receptors; those include receptor tyrosine kinases such as mitogenic growth factor receptors, as well as non-tyrosine kinase receptors such as G-protein-coupled seven-transmembrane receptors and receptors for cytokines; (4) membrane-associated nonreceptor tyrosine kinases, adaptor proteins, and phospholipases; (5) oncogenes in cytoplasmic signal transduction pathways, including RAS-RAF-MEK-MAPK pathway, the PI3K-AKT pathway, guanine nucleotide–binding proteins (G-proteins), PKC (Protein kinase C) and protein serine-threonine kinases, BCL-2 family members and the antiapoptotic regulation; (6) transcription factors and nuclear oncogenes. A list of putative oncogenes is summarized in Table 1 (Table 1).

Tab. 1 List of oncogenes.

Cell cycle progression	
Cyclins	D-type cyclins
CDKs	*CDK4*
CDK activators	*CAK, CDC25A, CDC25B*
E2F	
Telomere Maintenance	*HTRT*
DNA viral oncogene	SV40 large T, polyomavirus middle T and large T, papillomavirus E6 and E7 genes, adenoviruses E1A and E1B genes
Growth factors and extracellular mitogenic signals	
PDGFs	*SIS/PDGFβ*
FGFs	*FGF-3/INT-2, FGF4/HST, FGF-5, FGF-6*
WNT	*WNT-1, WNT-2, WNT-3*
EGFs	*EGF, TGF-α*
Cytokines	*IL-2, IL-3, GM-CSF, CSF-1*
Cell surface receptors	
Growth factor receptors	
EGF receptor family	*EGFR, ERBB2 (HER-2/neu)*
FGF receptor family	
PDGF receptor family	*PDGFα* and *β* receptors, *KIT*, *CSF*-1 receptor
Insulin receptor family	*IGF-IR*
MET/HGF receptor family	*MET*, *RON*, *c-SEA*
Neurotrophin receptor family	*TRKA*, *TRKB*, *TRKC*
VEGF receptor family	
Non-tyrosine kinase receptors	
Cytokine receptors	Receptors for IL-2, IL-3, GM-CSF, and erythropoietin
G-protein-coupled 7-TMR	*MAS*, thyrotropin receptor, serotonin 1c receptor
Plasma membrane–associated nonreceptor oncogenes	
Tyrosine kinases	
SRC family	*SRC*, *YES*, *FGR*, *LCK*, *LYN/SYN*, *FYN*, *HCK*, *BLK*, *YRK*, *LCK/TKI*
ABL family	*ABL*, *ARG*, *ABL/BCR*
FES family	*FES*, *FER*
JAK family	*JAK1*, *JAK2*, *TYK2*

(*continued overleaf*)

Tab. 1 (*Continued*)

ITK family	*ITK*, *BPK*, *TEC*	
SYK family	*SYK*, *ZAP*	
CSK family	*CSK/CYL*, *CTK*,	
Others	*FAK*, *BRK*, *FPS/FES/FER/TYK3*, *TKF*	
Adaptor proteins	*GRB2*, *SHC*, *CRK*, *NCK*	
Phospholipases	*PLC-γ*	
Oncogenes in cytoplasmic signal transduction		
RAS-RAF-MAPK pathway	*RAS* family	*H-RAS*, *K-RAS*, *N-RAS*, *R-RAS*
	RAF family	*RAF-1*, *A-RAF*, *B-RAF*
	MAPKs	*ERK1*, *ERK2*
PI3K-AKT pathway	PI3Ks	*PI3K/p85α*, *PI3K/p110α*
	AKT family	*AKT1*, *AKT2*
G-protein pathway		
	Heterotrimeric G-proteins	Gαi2, Gα12, Gα13, Gαz, Gαq, Gs
	GEFs	*SDC25*, *OST2*
	Phospholipases	*PLC-β*, *PLC-α*
	RAS family	See above
	RHO/RAC binding proteins	*BCR*, *VAV*, *DBL*, *ET2*, *NET1*, *TIAM1*, *TIM*
JAK-STAT pathway		
	JAK family	See above
	STAT family	*STAT*3, *STAT*5
Other protein serine-threonine kinases		
	PKC family	*PKC-ε*, *PKC-β1*, *PKC-γ*, *PKC-ζ*
Anti-apoptotic oncogenes		
	Bcl-2 family	*BCL-2*, *BCL-XL*,
	IAP family	c*IAP*1, c*IAP*2, *XIAP*, survivin, *LGALS*3
Chaperone proteins		*HSP*90
Nuclear transcription factors		
FOS family	*c-FOS*, *FOS-B*, *FRA-1*, *FRA-2*	
JUN family	c-*JUN*, *JUN*-B, *JUN*-D	
MYC family	c-*MYC*, N-*MYC*, L-*MYC*	
REL/NFκB family	*NFκB*1, *NFκB*2, *REL*, *REL*A, *REL*B	
Steroid hormone receptors	*ER*	
Homeodomain-containing oncogenes	*HOX*A9, *HOX*2.4, *HOX*7.1, *HOX*11,	
ETS family	*ETS, ELK*-1	
Others	*MYB* (*MBM*2), β-catenin	

2.5 Mechanisms of Oncogene Perturbation

2.5.1 Viral Oncogenes

Retroviral oncogenes are derived from cellular proto-oncogenes and their activation and function are similar to their cellular oncogene counterparts in the infected host cells. Viral infection will express the viral oncogenes in the host cell, leading to transformation. DNA viral oncogenes, including SV40 large T-antigen, polyomavirus middle and large T-antigens, papillomaviruses E6 and E7 proteins, adenoviruses E1A and E1B proteins, and EBV LMP1, promote tumorigenesis primarily by acting on RB and p53 tumor suppressors to suppress their surveillance role in cell cycle progression. Some viral oncoproteins may also activate signaling proteins

at the inner surface by protein–protein interaction as exemplified by association of T-antigen with SRC, SHC, and insulin-like growth factor (IGF-IR) and papillomavirus E5 oncoprotein association and activation of platelet-derived growth factor (PDGF) receptor and c-SRC. The *HBV X* gene-encoded protein may stimulate host-cell transcription to promote cell proliferation, leading to tumorigenicity.

2.5.2 Cellular Oncogene Activation by Viral Integration

Some viruses do not encode viral oncogenes, but they can integrate into the host-cell genome and alter cellular oncogene(s) and tumor suppressor gene(s) at or around the insertion site. These viruses include avian leucosis virus (ALV) and mouse mammary tumor virus (MMTV). The first example is the activation of c-*MYC* in Bursal lymphomas by ALV insertion.

2.5.3 Chromosome Translocation

There are 22 pairs of euchromosomes and two sex chromosomes in human somatic cells, and human proto-oncogenes have been identified in all of these chromosomes. In many carcinomas, cancer cells have abnormal karyotypes, such as translocations, duplications, deletions, and loss of chromosomes. Chromosomal translocations can put proto-oncogenes under control of the promoter/enhancer of another gene, or create recombinant, truncated, or deleted proto-oncogenes. In some of these circumstances, the proto-oncogenes can be activated. Examples include *ABL* activation on the *Philadelphia chromosome* in chronic myelogenous leukemia (CML), c-*MYC* translocation in Burkitt's lymphomas and plasmacytomas, and *BCL*-2 activation by chromosome translocation (t14 : 18) in follicular B-cell lymphomas. Other proto-oncogenes activated by chromosomal translocation include *BCL*-6, *HOS11, LYL*-1, *RHOM*-1, *RHOM*-2, *TAL*-1, and *TAL*-2.

2.5.4 Gene Amplification

Normally, all the genes on the euchromosomes and the X-chromosome in female have two copies in somatic cells. The genomic sequences of some genes may be amplified from two copies to 5–500 copies or even higher, typically generating more mRNA transcripts and higher protein levels of the oncogene, resulting in elevated activity of the oncogene. Examples include the amplification of N-*MYC* in neuroblastomas and *ERBB*-2 in breast cancer and many other cancer types.

2.5.5 Genetic Sequence Mutation

Simple genetic sequence mutation is also a major mechanism involved in the activation of many oncogenes. The mutation could be point mutation or deletion of a fragment of the gene.

2.5.6 Aberrant Gene Expression

Some genes may be expressed in some tissues for normal physiological processes or expressed during embryogenesis, but may be oncogenic when aberrantly expressed in the cells of a different tissue that normally do not express these genes. Aberrant expression is usually caused by epigenetic alteration(s) in the gene locus, such as demethylation of CpG islands in some genes, and chromatin hyperacytylation in the regulatory sequences.

2.5.7 Alterations Not at the Genetic Levels

The oncogenic activity of a gene may also be elevated by the regulation of other gene products, these include the stability of the

mRNA transcript, mRNA export from the nucleus to the cytoplasm, translation initiation and processing efficiency, protein stability and degradation, and downregulation of negative regulator(s) of a particular oncogene. For example, AKT can be stabilized by the chaperone protein HSP90, and AKT activity is elevated in cancer cells that have null mutation of its negative regulatory protein PTEN.

3 Biochemical Properties and Cellular Functions of Oncogenes

Normally, any cell type within an organ or tissue has to be maintained at a certain number (homeostasis). Whether a normal cell is to proliferate is usually regulated by the integrated mitogenic and inhibitory signals in the surrounding microenvironment (Fig. 6). Most of the extracellular signals trigger the signaling cascades through their receptors on cell surface, these include mitogenic (e.g. EGF (Epidermal Growth Factor)) or inhibitory (e.g. TGF-β) growth factors, cytokines, ligands for seven-transmembrane (7-TMR) receptors (e.g. some hormones such as bombesin). Signaling cascades can also be initiated from the cell surface by cell–cell interaction and cell-extracellular matrix (ECM) interaction. The execution of the integrated extracellular signals is carried out by the cell-signaling cascades and the newly synthesized gene products within the cell. Within the cells, the signaling pathways are very complicated, and there exist cross-regulations among different pathways at multitude levels that form a circuit network (Fig. 7). The alterations caused by these signaling

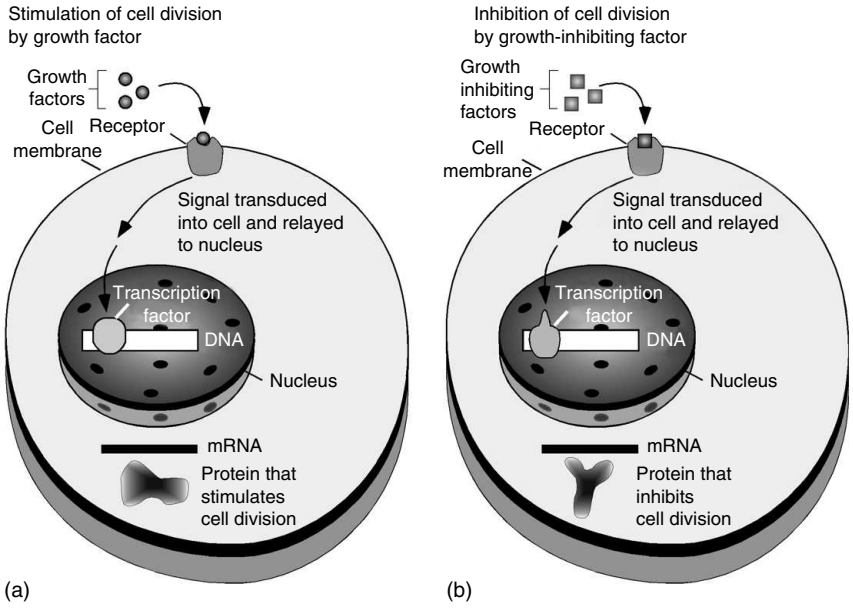

Fig. 6 Regulation of cell division by signals in the microenvironment. The impacts of extracellular signals such as growth factors (a) and growth inhibitory factors (b) on cell division are executed by the intracellular signaling, regulating protein activity and gene expression.

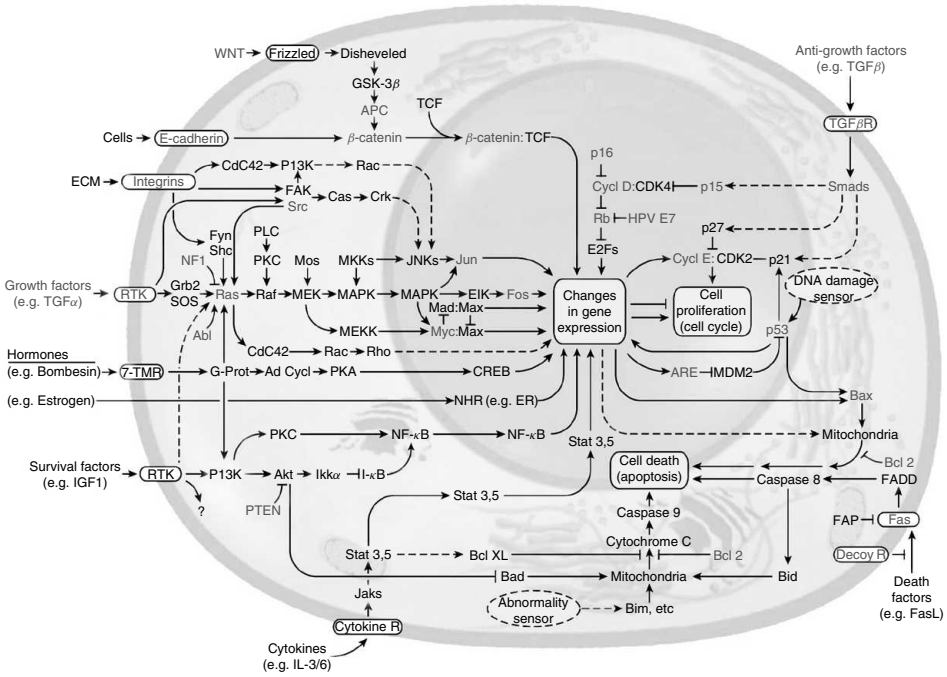

Fig. 7 The intracellular signaling circuit. Except steroid hormones such as estrogen, almost all extracellular signals are sensed by the cell surface receptors, which transmit the signals through the signal transduction cascades within the cell. Different signals or the same signals at different intensity may trigger common as well as distinct signaling pathways, leading to protein synthesis or activation. However, cross-regulations at many points of these different pathways exist, and many key regulatory molecules are shared among different pathways. The cell phenotype is regulated by the integrated signaling circuit in response to the complete signals in the environment. (Reproduced from Itanahan, D., Weinberg, R. A. (2000) The Hallmarks of Cancer, *Cell* **100**, 57–70. With permission of Cell Press).

molecules include qualitative and/or quantitative changes in proteins involved in cell signaling and the eventual outcome of cell phenotype. The qualitative changes could be mediated through protein phosphorylation by protein kinases (tyrosine and serine/threonine kinases) and dephosphorylation by phosphatases, as well as by other posttranslational modifications. The quantitative changes are mainly regulated at the transcriptional level mediated by the activation of transcriptional factors in the nucleus, but it can also be mediated through protein stability and degradation. In cancer cells, alteration(s) of an oncogene or several synergistic oncogenes could potentiate cells to proliferate without the requirement of normal surrounding signals.

3.1 Oncogenes Promoting Cell Cycle Progression and Cell Division

3.1.1 Oncogenes Derived from Cell Cycle Machinery

As described above (see Sec. 2.2), cyclins, CDKs, and E2F in the cell cycle machinery are positive regulatory proteins

for cell proliferation, and thus are candidate oncogenes. Of the cyclins, the D-type cyclins have been identified activated in cancers. Activation of CDK4 mediated by amplification or mutation (e.g. mutant CDK4 lacking the INK4 binding site) has been identified in tumors.

While CDKs are activated by cyclins, the activities of CDKs are also negatively regulated by the CKIs, including the INK4 ($p16^{INKA}$, $p15^{INKB}$, $p18^{INKC}$, and $p19^{INKD}$) that inhibit CyclinD/CDK4/6 and CIP/KIP ($p21^{WAF1/CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$) that inhibit all CDKs. The CKIs function as one of the cellular intrinsic surveillance mechanisms to make sure that the accurate genetic information is transmitted to the daughter cells. CKIs are regulated by growth-inhibitory factors, such as TGF-β, and by growth-arrest signals, such as DNA damage. When bound to inhibitory proteins such as INK4 ($p16^{INKA}$, $p15^{INKB}$, $p18^{INKC}$, and $p19^{INKD}$) and CIP/KIP ($p21^{WAF1/CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$), inactive CDK4 is phosphorylated at Tyr^{16} and Tyr^{17} by WEE1/MIK1/MYT1 and unphosphorylated at Thr^{172} (probably by p24KAP) (Fig. 8). Cyclins will compete with INK4 and CIP/KIP to bind to CDK, resulting in CDK phosphorylation at Thr^{172} by CAK (cyclin activated kinase) and dephosphorylation at Tyr^{16} and Tyr^{17} by CDC25 phosphatase, resulting in activation of CDKs. Therefore, *CAK* and *CDC25* could serve as proto-oncogenes to promote cell proliferation.

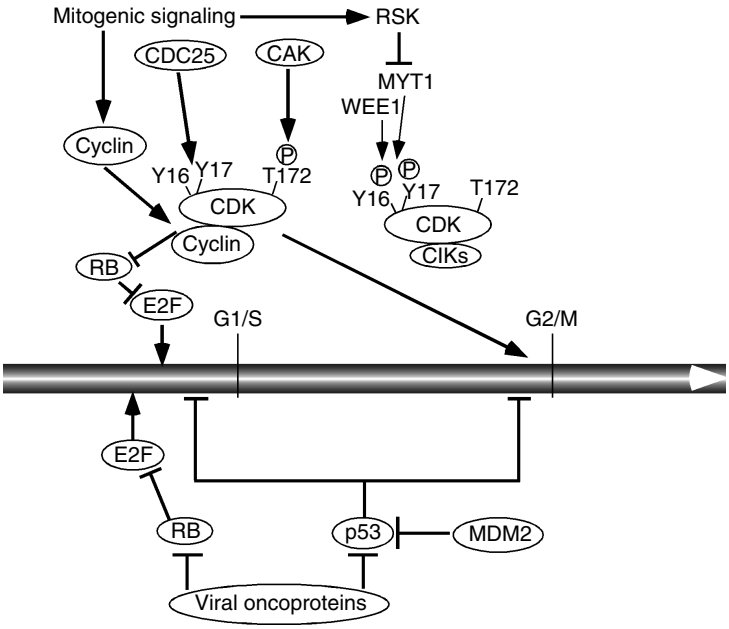

Fig. 8 Oncogenic proteins promoting cell cycle progression and cell division. Cellular oncoproteins E2F, cyclins, and CDKs promote cell cycle progression, and CDK activation is regulated by CDC25 and CAK. Viral oncoproteins may promote cell proliferation through inhibiting the negative regulatory proteins RB and p53.

3.1.2 Oncoproteins Leading to Loss of Control of Cell Cycle Checkpoints

Loss of chromosome integrity and accumulated genetic mutations caused by DNA damage are frequent phenomena found in cancer cells. In normal conditions, these cells cannot go through the cell cycle, instead the cells will either be arrested until the damaged DNA is fixed or the apoptotic pathway will be triggered in these cells. In addition to RB and CKIs, p53 is another principal regulatory molecule for the cell cycle checkpoints. Propagation of harmful genetic mutations and loss of chromosome integrity in cancer cells could be attributed to the defective function of these negative regulatory molecules, or to the gain of functions of oncogenes that suppress the function of these negative regulatory molecules. Examples of such oncogenes include MDM2 (mouse double minute 2) and some viral oncogenes (Fig. 8).

Under normal circumstances, p53 function is principally regulated at protein level through protein stability and degradation. MDM2 is a target gene of p53, MDM2 binds directly to p53, repressing its transcriptional activity and targeting p53 for ubiquitination and degradation. MDM2 in return is negatively regulated by p19/ARF. In response to DNA damage, p53 is upregulated through DNA-dependent protein kinase and ATM (ataxia telangiectasia mutated gene). The function of p53 in cell cycle arrest and apoptosis may be mediated by both transcription-dependent and -independent mechanisms. The target genes of p53 include $p21^{WAF1/CIP1}$, *GADD45* gene (growth arrest and DNA damage-inducible genes), *BAX, FAS, DR5,* and *IGFBP3*. $p21^{WAF1/CIP1}$ is involved in both G_1/S and G_2/M arrest by inhibiting CDKs to block cycle progression; $p21^{WAF1/CIP1}$ also binds to proliferating cell nuclear antigen (PCNA) to inhibit DNA replication. GADD45 expression is associated with G_1 and G_2/M arrest, and it also binds to PCNA to stimulate damaged DNA repair. p53 also can suppress the expression of some genes without p53-binding site; these include *RELA*, *IL-6*, *CYCLIN A*, and *PCNA*. MDM2 is a ubiquitin E3 ligase found highly expressed in many cancer types; its overexpression leads to degradation of p53 and thus suppresses the tumor suppressor functions of p53 in cell cycle arrest, apoptosis, and transcription activation of p53 target genes.

Many DNA viral oncogenic proteins promote tumorigenesis by inactivating the RB and p53 tumor suppressor genes. Viral oncoproteins interacting with and inactivating RB include adenoviral E1A, HPV E7, and SV40 large T-Ag. Viral oncoproteins interacting with p53 include HPV E6 (leading to p53 degradation by ubiquitin-dependent proteolysis), adenoviral E1B (repressing the transcriptional activity of p53), and SV40 T-Ag.

3.2 Growth Factors and Extracellular Mitogenic Signals

Growth factors are polypeptides that regulate cellular processes by binding to their specific receptors on target cells and trigger the intracellular signaling cascades by activating the receptors. Oncogenes derived from growth factors include those that are mitogens involved in cell proliferation. Unlike endocrine hormones, growth factors usually act on cells locally. The three types of growth factor action are autocrine, paracrine, and juxtacrine (Fig. 9). In autocrine regulation, the growth factor and its corresponding receptor are produced in

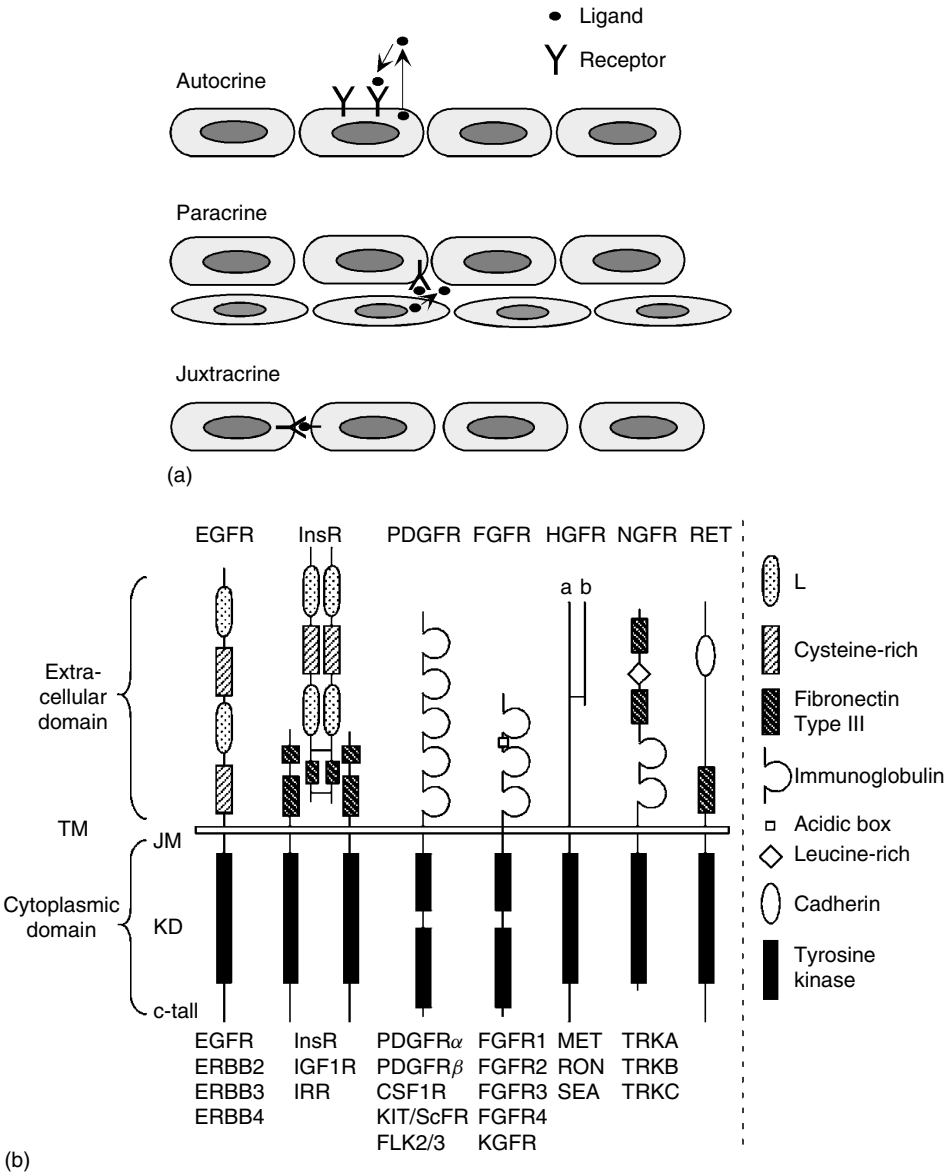

Fig. 9 Mitogenic signals and the receptor tyrosine kinases. The three types of growth factor action on cell surface receptors (a) and the structure features of representative growth factors (b), modified from Hubbard, S.R. (1999) Structural analysis of receptor tyrosine kinases, Prog. Biophys. Mol. Biol. **71**, 343–358. The extracellular domain is the site for growth factor ligand binding, and cytoplasmic domain possesses kinase domain and contains sites for binding by proximal signaling molecules.

the same cell, so that the growth factor can act on the cell from where it is produced. In paracrine regulation, growth factors are released from cells and act on cells in their immediate vicinity. An example of paracrine regulation is the regulation of KGF (keratinocyte growth factor) and KGF receptor; KGF receptor is expressed only in epithelial cells, activation of KGF receptor is regulated by the binding of its ligand KGF, which is produced by mesenchymal cells. Usually, extracellular matrix is involved in restraining the dissemination of the growth factors, and sometimes some matrix component is actively involved in the interaction between the growth factor and its receptor. A good example is the involvement of heparin in the interaction of FGFs (fibroblast growth factors) and FGF receptors (FGFRs). Juxtacrine regulation is a special type of paracrine action, in which growth factor is either a transmembrane protein or tightly restrained to the surface of the cell membrane, and cell–cell contact is required for the growth factor to exert its action.

3.2.1 PDGF (Platelet-derived Growth Factor) and the *SIS* Oncogene

PDGF contains two subunits, the A subunit and the B subunit, either in homodimer or heterodimer. The B subunit of PDGF is encoded by the *SIS* oncogene, originally found in simian sarcoma virus. While PDGF AA homodimer activates only the receptor for PDGFα, PDGF BB homodimer and AB heterodimer activate both PDGFR-α and PDGFRβ. Both PDGF AA and PDGF BB were shown having oncogenic activity when analyzed by *in vitro* experiments. PDGF and PDGF receptor may form autocrine regulation in sarcomas, lung carcinomas, astrocytomas, and acute myelogenous leukemia (AML).

3.2.2 FGFs (Fibroblast Growth Factors)

The FGF family comprises at lease nine members. Among the FGF family members, FGF-3/INT-2, FGF-4/HST/K-FGF, FGF-5, and FGF-6 have been identified as oncogenes. FGFs and their corresponding receptors can form autocrine regulation and may be involved in many cancer types, including colorectal, breast, ovarian, lung, and prostate carcinomas.

3.2.3 The WNT Gene Family

At least 10 members have been identified in the WNT family, and WNT-1, -2, -3, and -5 can be activated as oncogenes. The receptors for WNT are seven-transmembrane FZD (frizzled) proteins. The WNT-initiated signaling also releases the oncogenic function of β-catenin, as the loss of *APC* gene in colon cancer (Fig. 7). Deranged WNT signaling have been observed in colorectal, breast, gastric, cervical, and lung carcinomas.

3.2.4 EGF (Epidermal Growth Factor) and TGF-α

EGF and TGF-α (transforming growth factor-α) are ligands for EGF receptor (EGFR). Other EGF family members include heregulins. Expression of EGF and TGF-α are found in several cancer types, including breast and colorectal carcinomas.

3.2.5 Hematopoietic Growth Factors

More than 20 different hematopoietic growth factors have been identified, and at least 4 of them can function as oncogenes, including IL-2 (interleukin-2), IL-3, GM-CSF (granulocyte-macrophage colony stimulating factor), and colony stimulatory factor 1 (macrophage colony stimulating factor).

3.3 Oncogenes Derived from Cell Surface Receptors

3.3.1 Growth Factor Receptors

Growth factor receptors are RTKs (receptor tyrosine kinases) comprising an extracellular domain, the transmembrane domain, and the cytoplasmic portion composed of the juxtamembrane domain, the kinase domain, and the C-terminal region (Fig. 9). The extracellular domain is the site for specific ligand binding; the cytoplasmic domain has intrinsic kinase activity and binding sites for proximal signaling proteins. Upon ligand binding to the extracellular domain, monomeric RTKs dimerize as homo- or heterodimers and the tyrosine residues become autophosphorylated. The phosphorylated tyrosines provide docking sites for many SH2-domain-containing proteins, and the amino acid residues flanking the phosphorylated tyrosine residue may determine the specificity of binding. SH2-containing proteins could be protein kinases (SRC, ABL, PI3K/p85, PLC-γ), or adapter proteins without kinase activity (e.g. GRB2, CRK, SHC, NCK) (see Sec. 3.3.3). The major signaling pathways triggered by different RTKs are quite similar, including RAS-RAF-MEK-MAPK and PI3K-AKT pathways (see Sec. 3.4), and how different growth factors and their receptors are fine-tuned to achieve the specificity in signaling and cellular responses are still under intense investigation.

3.3.1.1 **Epidermal growth factor receptor family** The EGF receptor belongs to the ERBB family of four closely related cell membrane receptors: EGFR (HER1 or ERBB1), ERBB2 (HER2/neu), ERBB3 (HER3), and ERBB4 (HER4). EGFR and HER-2/neu are involved in many aspects of almost all cancer types, including lung, colorectal, prostate, breast, and ovarian cancer. These receptors are transmembrane glycoproteins that consist of an extracellular ligand binding domain, a transmembrane domain, and an intracellular domain with tyrosine kinase activity for signal transduction. Activation of ERFR occurs when a ligand, such as EGF, TGF-α, or amphiregulin, binds to its extracellular domain. This causes the receptor to dimerize with either another EGFR monomer or with another member of the ERBB family. Following receptor dimerization, activation of the intrinsic protein tyrosine kinase activity and tyrosine autophosphorylation occur. These events lead to the recruitment and phosphorylation of several intracellular substrates, leading to mitogenic signaling and other cellular activities. Receptors that lack kinase function, because of mutations at the ATP binding sites, do not display a full range of biochemical responses following ligand binding; this demonstrates that receptor tyrosine kinase activity is required in cellular signaling. A major signaling route of the ERBB family appears to be the RAS-RAF-MEK-ERK pathway. Another important pathway in ERBB receptor signaling is the one constituted by phosphatidylinositol 3-kinase and the downstream protein kinase AKT. After its activation, AKT transduces signals that regulate multiple biological processes including apoptosis, gene expression, and cellular proliferation. AKT is likely to send survival (antiapoptotic) signals by phosphorylating multiple targets, including the BCL-2 family member BAD (a proapoptotic factor), the cell-death pathway enzyme caspase-9, Forkhead transcription factors, and IκB kinase α. AKT also plays a prominent role in the regulation of cell cycle progression. Thus, EGFR signaling can lead to a variety of downstream reactions,

which are subject to complex regulatory mechanisms.

3.3.1.1.A. **EGFR and cancer** EGFR signaling impacts on many aspects of tumor biology. Activation of the EGFR has been shown to enhance processes responsible for tumor growth and progression, including the promotion of proliferation, angiogenesis, invasion/metastasis, and inhibition of apoptosis. The expression of EGFR in tumors has been correlated with disease progression, poor survival, poor response to therapy, and the development of resistance to cytotoxic agents. High levels of EGFR have been observed in a variety of tumors, including prostate, breast, gastric, colorectal, and ovarian. However, mechanisms other than EGFR expression might affect EGFR signaling. For example, genomic rearrangements in the *EGFR* can cause expression of modified receptors. One frequently occurring truncated form, EGFRvIII has previously been described by Wong and colleagues and is the result of a 267 amino acid in-frame deletion in the extracytoplasmic domain with the generation of a novel glycine at the fusion junction (Fig. 10). It has been shown that this altered receptor is present in a variety of cancers, including breast, lung, and ovarian carcinomas. The fact that this receptor is frequently found in tumors, but not present in normal tissue, makes it an attractive candidate for various antitumor strategies.

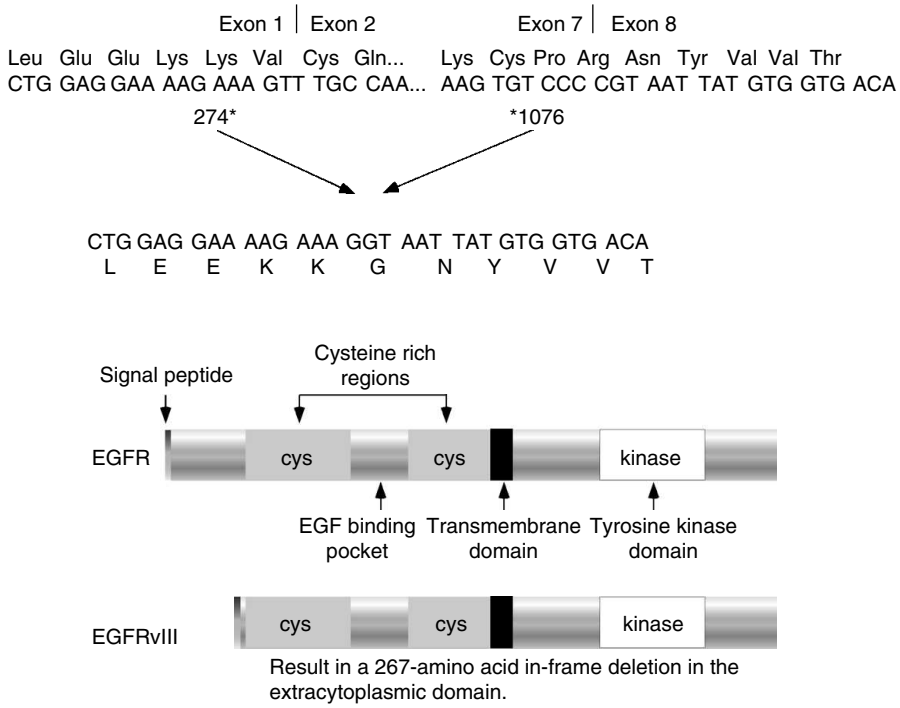

Fig. 10 Schematic representation of alternative spliced EGFR transcript, which encodes for the mutant EGFRvIII. EGFRvIII differs from EGFR in that 267 amino acid residues are absent from the extracytoplasmic domain.

3.3.1.1.B. **HER-2/neu and cancer** HER-2/neu has intrinsic kinase activity, and no ligand has been found for HER-2/neu. Overexpression of wild-type HER-2/neu or somatic mutations at the transmembrane (TM) region are believed to enhance and maintain the receptor dimerization. HER-2/neu can interact with other members of EGFR family, including EGFR, HER-3, and HER-4 to form heterodimer. Activated HER-2/neu can interact with many cellular signaling proteins, including GRB2, SHC, PLC-γ, c-SRC. GRB2 binding recruits SOS to the plasma membrane and activates the RAS-RAF-MEK-MAPK pathway (see Sec. 3.4). PI3K-AKT pathway is also activated by HER-2/neu, although it does not contain the p85/PI3K binding site, and, maybe, it is mediated through heterodimerization with HER-3.

HER-2/neu is overexpressed in many different types of human cancers, including breast, ovarian, lung, gastric, and oral cancers. Amplification of HER-2/neu or overexpression of HER-2/neu has been identified in about 20 to 30% of breast, ovarian, and gastric cancers. HER-2/neu is also frequently expressed in NSCLC (nonsmall cell lung cancer). Increased HER-2/neu expression can enhance the metastatic potential of human cancer cells, and repression of HER-2/neu suppresses the malignant phenotypes of HER-2/neu-overexpressing cancer cells.

3.3.1.2 **Fibroblast growth factor receptor family** Four members have been identified in the FGFR family. FGFRs are expressed by most cancer cells, and activation of FGFRs by mutation has been identified in several cancer types, including melanoma, bladder, and cervical carcinomas. Proteins binding to the cytoplasmic region of FGFRs include FRS2, GRB2/SOS, PLC-γ, CRK, and SRC. FRS2 is critical for FGFR-initiated activation of MAPKs and phosphatidylinositol-3 (PI-3) kinase activation in cell proliferation.

3.3.1.3 **Platelet-derived growth factor receptor family** The PDGF receptor family includes PDGF α and β receptors, stem cell factor receptor (KIT), macrophage-colony stimulating factor-1 receptor, and FLT3. Autocrine activation of PDGF receptor has been identified in many cancer types, including lung, gastric, prostate, glioblastoma, and astrocytomas. Activation of PDGF receptor are involved in various cellular responses, including cell growth, proliferation, and cell migration. The proximal proteins interacting with PDGF receptor and transmitting the signaling cascades include PI3K, CRK, PLC-γ, and SRC. Interaction of PDGF receptor with SRC, integrin and FAK (focal adhesion kinase) might be involved in lamellipodia formation and cell migration. STAT-1, -3, and -6 can be activated by PDGF receptor, independent of SRC activation. Protein tyrosine phosphatases (PTP) that are potentially associated with PDGF receptor and involved in downregulation of PDGF receptor include PTP-PEST, SHP-2, PTP-1B, low M(r) PTP.

KIT, a 145-kD transmembrane glycoprotein, is the receptor tyrosine kinase encoded by the c-*KIT* proto-oncogene and is the normal cellular homolog of the viral oncoprotein v-*Kit*. These kinases have an extracellular domain containing five immunoglobulinlike domains, a single transmembrane domain, and a cytoplasmic domain with a split kinase domain and hydrophilic kinase insert sequence. The juxtamembrane and kinase domains of these receptors are strongly conserved. c-KIT is normally expressed by hematopoietic progenitor cells, mast cells, germ cells, interstitial cells of Cajal, and also by

certain human tumors. Normal function of the c-Kit gene product, as demonstrated in mouse models, is essential for hematopoiesis, melanogenesis, gametogenesis, development of ICC (interstitial cell of Cajal), and mast cell growth and differentiation.

Two general mechanisms of c-KIT involvement in the development or maintenance of the malignant phenotype have been described. First is the acquisition of c-KIT mutations resulting in ligand-independent activation. Second is tumor cell expression of KIT with autocrine and/or paracrine stimulation of the receptor by its cognate ligand, steel factor (STL). c-KIT activating mutations have been described in the conserved juxtamembrane domain, extracellular domain, and in the kinase domain. Structural alterations of the juxtamembrane domain may be a common pathway for activation of type III receptor tyrosine kinases as similar mutations have been described for FLK2/FLT3 and PDGFR. Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal malignancies of the GI tract and these tumors are characterized by the presence of constitutively activated KIT. The majority possesses gain of function mutations in c-*KIT* (Fig. 11), while a smaller percentage have a mutation in *PDGFR*.

KIT oncogenic activation results in autophosphorylation of critical tyrosine residues, which are "docking" sites for various signaling intermediates. These signaling intermediates are phosphorylated by the activated KIT proteins or by each other, and they transmit the KIT oncogenic signal to downstream targets. Various KIT oncoproteins differ in their structure and in their activation of specific downstream signaling pathways, depending on the mutation. KIT-mediated phosphorylation of signaling proteins such as AKT, STATs (Signal transducers and activators of transcription), MAPK, and JNK can influence proliferation, apoptosis, differentiation and/or cell adhesion, which may contribute to the malignancy of GIST. These key signaling proteins, and others downstream of KIT, have variable biological effects, depending on the cellular

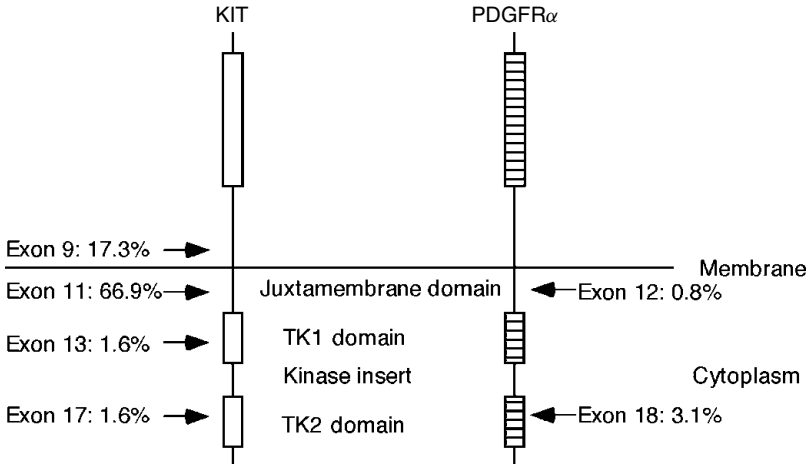

Fig. 11 Structure of KIT and PDGFR and the frequency of mutations observed in sporadic and familial gastrointestinal stromal tumors *(GISTs)*.

context. For example, RAS and MAPK activation is a key transforming event in some cancers, but many tyrosine kinase oncoproteins, including BCR-ABL, do not require this pathway.

3.3.1.4 **Insulin receptor family** The insulin-like growth factor (IGF) family, including insulin, IGF-I, and IGF-II, and their receptors and binding proteins (IGFBP) are involved in various normal cellular functions in development and in the body. Aberrant expressions of those proteins were found in many cancer types and they play an important role in tumorigenesis. IGF-I receptor (IGF-IR) is the principal receptor for IGF-I and IGF-II, IGF-II also binds to the isoform A of insulin receptor (IR-A) with high affinity. IGF-IR and its ligands are frequently overexpressed in many cancer types, including breast, colorectal, gastric, lung, ovarian, prostate, and pancreatic carcinomas. IGF-IR and its ligands IGF-I or IGF-II form an autocrine regulation, and the effects of IGF-I and IGF-II are regulated by IGF-binding proteins (IGFBPs) and IGFs may act synergistically with other mitogenic growth factors and steroids

Activation of IGF-IR may promote tumor progression by promoting cell growth and proliferation, inhibiting apoptosis, and inducing angiogenesis. Activation of IGF-IR may also promote metastasis by enhancing cell motility and regulating cell–cell and cell–matrix adhesion. The impact of IGF-IR on these processes has been assessed by evaluating the activation of several signaling pathways and the expression of many genes involved in these processes. Among the genes upregulated in response to activation of IGF-IR are vascular endothelial growth factor (VEGF) and COX-2. Activation of IGF-IR leads to the activation of several signaling pathways, including PI3K-AKT pathway and the RAS-RAF-MAPK pathway.

3.3.1.5 **MET/HGF receptor family** The MET family consists of three related proteins: MET, RON, and c-SEA. HGF/SF (Hepatocyte growth factor/scatter factor) is the ligand for MET, and many cell types, including epithelial cells, are regulated by HGF-MET interaction. Under physiological conditions, HGF is produced by mesenchymal cells and HGF-MET can form a paracrine loop regulation. Unlike most other RTKs, MET exists as a disulfide-linked heterodimer originated from the same precursor protein through proteolytic cleavage. The C-terminal end of MET has a multiple substrate docking site for the binding of adapter proteins, including GRB2, SHC, CRK/CRKL, GAB1. In addition to ligand-dependent activation, MET can also be transactivated (HGF-independent) by other membrane receptors, such as adhesive receptors (e.g. integrins and CD44), RON, and EGFR.

Increased MET expression has been found in many types of carcinomas, and dysregulation of MET is related to metastatic ability of tumor cells. The mechanisms of MET dysregulation include the following: (1) wt-MET and HGF-dependent: wt-MET is activated by HGF through autocrine or paracrine regulation; (2) HGF-independent MET activation that are caused by overexpression of wild type or mutant MET, gene rearrangement (e.g. *TPR-MET*), abnormal MET processing, defects of negative regulators, and truncation. TPR-MET encompasses the TPR leucine zipper domain and the MET cytoplasmic kinase domain, which results in constitutive activation of MET because of leucine zipper domain interactions.

3.3.1.6 **Neurotrophin receptor family** The TRK (tropomyosin receptor kinase, including TRKA, TRKB, and TRKC) family are receptors for neurotrophins, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4), and are normally expressed in neurons. While activation of TRK by neurotrophins is involved in tumors of both neuronal origin such as neuroblastoma and medulloblastoma and nonneuronal origin such as prostate and pancreatic cancer, TRK is constitutively activated in many nonneuronal cancer types caused by chromosome translocation. The *TRK* (*TRKA*) proto-oncogene encodes a 140-kDa protein composed of 790 amino acid residues. In colon cancer, the *TRK* oncogene is composed of sequences from nonmuscle tropomyosin gene and the *TRK* proto-oncogene (encoding amino acid residues 392–790). The nonmuscle tropomyosin sequence may contribute to the activation of TRK by allowing its kinase domain to fold into a constitutively active configuration. Proto-oncogene *TRK* can also be activated by genetic rearrangement with other genes, such as with the ribosomal large subunit protein *L7a* to form *TRK-2H* oncogene in breast carcinoma, with the *TPR* to form *TRK-T1* oncogene in papillary thyroid carcinomas, and with the *ETV6* to form the *ETV6-NTRK3* oncogene in human secretory breast carcinoma and several other cancer types. Activation of TRK may contribute to tumorigenesis by promoting cell proliferation and suppression of apoptosis, and these impacts are carried out by the activation of multiple signaling pathways, including PI3K-AKT pathway, RAS-RAF-MEK-MAPK pathway, and activation of PLC-γ.

3.3.2 Cell Surface Receptors without Tyrosine Kinase Activity

Some cell surface receptors do not have intrinsic kinase activity, but they may be oncogenic by activating the downstream targets to initiate the signaling cascades or induce expression of oncogenes. These include the cytokine receptors (e.g. receptors for IL-2, IL-3, and GM-CSF, receptor for erythropoietin) and the G-protein-coupled seven-transmembrane receptors (MAS, Thyrotropin receptor, Serotonin 1c receptor).

3.3.3 Membrane-associated Nonreceptor Oncogenes

3.3.3.1 **Membrane-associated nonreceptor tyrosine kinases** Some protein tyrosine kinases are not cell surface receptors, but they are associated with the inner surface of the plasma membrane. They are associated with the membrane by posttranslational modification such as myristilation in which myristic acid is added to the 2nd amino acid residue glycine after Met is removed, thus facilitating their interaction with cell surface receptors. These protein kinases also constitute a large group of oncogenes, including members of SRC and ABL subfamilies (see Table 1). The SRC subfamily includes SRC, YES, FGR, FYN, HCK, BLK, YRK, LCK (TKL), and LYN/SYN. The ABL subfamily includes ABL and ARG. ABL contains a SH3 domain at its N-terminus, followed by a SH2 domain, the kinase domain, and the C-terminal region. ABL proto-oncogene can be activated either by incorporation into retrovirus or by chromosome translocation. In Abelson leukemia virus, the N-terminus including the SH3 domain of c-*ABL* proto-oncogene is deleted during the integration into the viral genome to form the v-*ABL* oncogene. In Philadelphia

chromosome translocation, c-*ABL* is fused with *BCR* to form the oncogene *BCR/ABL*, encoding a recombinant protein BCR/ABL in which ABL is activated. Activation of ABL may activate multiple signaling pathways, including the JAK-STAT pathway.

3.3.3.2 **Membrane-associated adaptor proteins** Some SH2- and/or SH3-containing proteins may not have kinase domain, but may function as adaptor proteins to facilitate protein–protein interactions, and thus may also be oncogenic. These proteins include GRB2, CRK, SHC, and NCK.

GRB2 contains a SH2 domain and two SH3 domains, the SH2 domain can bind to phosphotyrosine on activated RTKs or proteins associated with RTKs (e.g. SHC). The SH3 domains bind to SOS, so that GRB2 and SOS always form a complex in the cells. SOS is the guanine nucleotide exchange factor for RAS (see Sec. 3.4.3). When recruited to the activated RTKs, the GRB2-SOS is activated to promote RAS GTP/GDP exchange, resulting in RAS activation in the RAS-RAF-MEK-MAPK pathway (see Sec. 3.4.1). In addition, GRB2 is also involved in cell transformation caused by polyomavirus middle T-antigen.

CRK family has four members, v-CRK, CRKI, CRKII, and CRKL. The SH2 domain of CRK family proteins is involved in association with cell surface receptors, while the SH3 has been identified to be associated with many signaling molecules including SOS, C3G (GEF for RAP1), ABL, and DOCK180.

3.3.3.3 **Membrane-associated phospholipase: PLC-γ (phospholipase C-γ)** While PLC-γ binds to and is activated by many RTKs such as EGFR and ERBB2, PLC-β is activated by G-proteins (see Sec. 3.4.3). Phospholipases can catalyze the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) to generate diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3). DAG activates PKC, and IP3 can stimulate Ca2+ release. PLC-γ is overexpressed in some cancer types, including breast and colon cancer. The signaling proteins activated by PLC may be involved in mitogenic signaling pathways in cell growth and cell invasion and contribute to tumor progression.

3.4 Oncogenes in Cytoplasmic Signal Transduction Pathways

3.4.1. RAS-RAF-MEK-MAPK (ERK) Pathway

Mitogen-activated protein kinase (MAPK) pathway and PI3K-AKT pathway are two major signaling pathways activated by cell surface receptors to regulate diverse cellular processes. With regard to oncogenesis, the MAPK pathway is involved in cell proliferation and cell survival, and PI3K-AKT is involved in cell growth and cell survival. The regulation of MAPKs is mediated by a conserved core module, which is composed of the MAPKs, MEK (MAPKK), MEKK (MAPKKK) (Fig. 12). ERK, JNK, and p38 are the major MAPKs in higher eukaryotes. The MEKK regulating ERK is RAF, and RAF is regulated by RAS. RAS is a small G-protein regulated by GRB2/SOS (see Sec. 3.4.3). Activated GTP-bound RAS recruits RAF to the membrane by directly interacting with RAF, resulting in RAF phosphorylation and activation. In addition to mitogenic stimulation activated RTKs, MAPK pathway is activated by several other mechanisms. Activation of heterotrimeric G-proteins can activate MAPK directly or

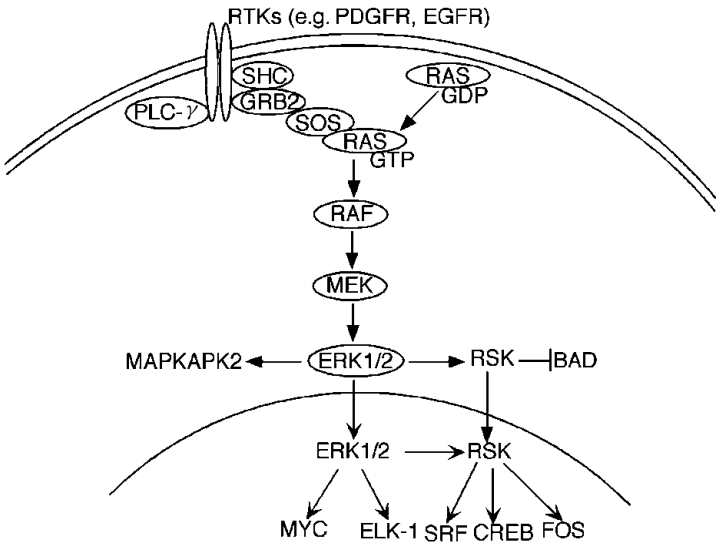

Fig. 12 The RAS-RAF-MEK-MAPK pathway. The small GTPase RAS is associated with cell membrane inner surface. Upon activation of RTKs, the guanosine nucleotide exchange factor SOS is activated, which, in turn, activates RAS. RAF-MEK-ERK is the major pathway for activated RAS, and can be cross regulated by many other pathways such as heterotrimeric G-proteins. The activated ERK and its substrate RSK family members regulate many immediate-early genes and the activity of many proteins involved in diverse cellular processes including cell survival and apoptosis.

indirectly through activation of PKC. Activated ERK can phosphorylate RSK1 to promote cell survival, and it can also activate many transcription factors to stimulate gene expression to promote cell proliferation.

3.4.1.A **RAS** There are three members of RAS: Ha-RAS (homologous to the Harvey murine sarcoma virus oncogene), K-RAS (homologous to the Kirsten murine sarcoma virus oncogene), and N-RAS (initially isolated from a neuroblastoma cell line). RAS is associated with the plasma membrane inner surface, which is mediated by posttranslational modifications and is essential for its function. The modifications include the farnesyl isoprenoid moiety added to the CAAX motif at the carboxyl terminus by farneysyltransferase, palmitoylation at cysteine residue(s) N-terminal to the CAAX motif, the removal of AAX from the CAAX motif by RCE1 cleavage followed by carboxymethylation of the modified cysteine residue in the CAAX motif. Mechanisms leading to RAS activation include gene mutation and gene amplification that have been identified in many cancer types. Some mutations lead to irreversible binding of GTP to RAS, including mutations at amino acid residues 12, 13, 59, 61, and 63. In certain circumstance, activations of RAS and MYC have a significant synergistic effect on tumorigenesis. Even in the case that there is no mutation in RAS, RAS may also contribute to tumorigenicity if its upstream regulatory proteins such as RTKs are activated.

3.4.1.B **RAF** There are three members in the RAF family, RAF-1, A-RAF, and B-RAF. B-RAF is implicated in tumor progression, but not in tumor initiation. The protein structure of RAF family members contain a kinase domain in its carboxyl-terminal half and a regulatory region in its amino-terminal half. In normal cells, RAF is activated by RAS in the RAS-RAF-MEK-MAPK pathway. AKT might be involved in RAF phosphorylation at Ser^{259}. RAF can become oncogenic when the N-terminal regulatory region is deleted, as observed in retroviruses and in in vitro functional analysis.

3.4.1.C **ERK and cell survival** MAPKs are activated in response to many mitogenic stimulations, and they are involved in numerous physiological functions, including cell survival, apoptosis, and metastasis. Activation of ERK may promote cell survival and suppress apoptosis. One of the pathways for ERK to promote survival is to activate RSKs; activated RSKs phosphorylate a number of proteins, including BAD and CREB that are involved in cell survival and inhibition of apoptosis. RSKs belong to the AGC protein serine/threonine kinase family, which includes PKA, PKB/AKT, PKC, and RSKs. RSKs and AKT share many common substrates, and many of these substrates are involved in cell survival.

ERK and immediate-early responsive genes in cell proliferation. MAPK activation also leads to the synthesis of immediate-early genes (50–100 in total, including many oncogenes such as FOS, c-MYC, JUN, and D-type cyclins) that are involved in cell proliferation. The synthesis of those immediate-early genes is very rapid and transient, and no new protein synthesis is required. For example, c-FOS is induced within 15 min of growth faction stimulation and returned to basal level within 2 h. Induction of FOS transcription is regulated by the binding of transcription factor complex, including SRF (serum response factor) and ELK1, to the SRE (serum response element), and binding of STAT to the SIE (SIS inducible element) in its promoter region. ELK1 is a substrate of ERK1/2, and SRF can be phosphorylated and activated by RSK, which is in turn phosphorylated and activated by ERK1/2. The induced FOS protein may be involved in the suppression of further FOS transcription by negative feedback autoregulation. The synthesis of immediate-early genes is regulated at both transcriptional and posttranscriptional levels, while the subsequent downregulation of immediate-early genes to basal level requires new protein synthesis.

3.4.2 The PI3K-AKT Pathway

AKT is involved in the tumorigenesis of many cancer types. There are three members in the AKT family, AKT1, AKT2, and AKT3. AKT family members have an N-terminal pleckstrin homology (PH) domain, a catalytic domain, and a C-terminal regulatory domain. AKT activation is regulated by PI3-K kinase, PDK1, MSK, and MAPKAP kinase-2 (Fig. 13). PI3K contains two subunits, the p110 catalytic subunit and the p85 regulatory subunit. AKT activation involves the phosphorylation of Thr^{308} in the catalytic domain and Ser^{473} in the C-terminal regulatory region. In response to RTK activation, PI3K is recruited to the RTK via the SH2 domain of p85 subunit and becomes activated. The activated PI3K catalyzes the generation of 3'-phosphoinositides, which, in turn, recruits PKB/AKT from the cytosol to the plasma membrane via the PH domain of AKT. The membrane-bound

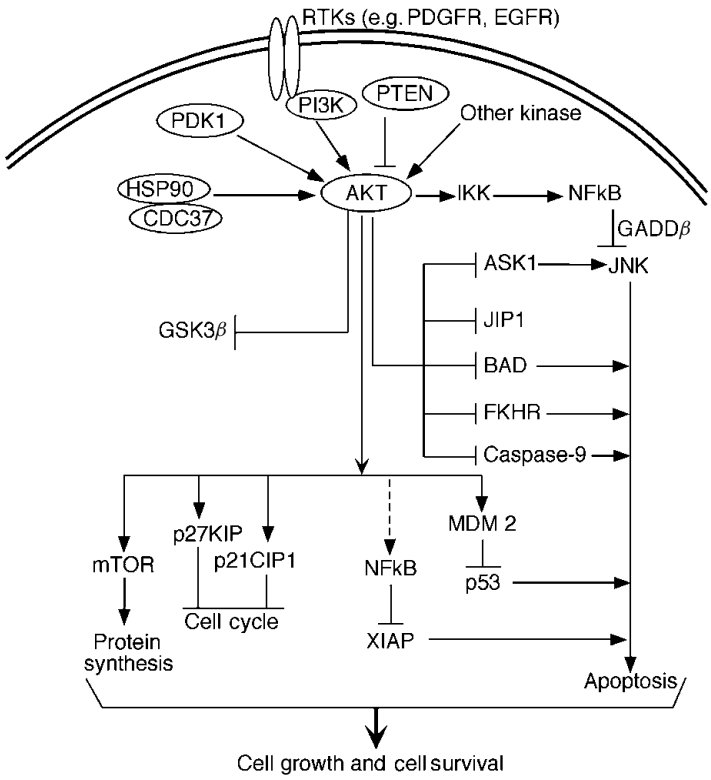

Fig. 13 The PI3K-AKT pathway. AKT activation is regulated by PI3-K kinase, PDK1, and other kinases such as MSK and MAPKAP kinase-2. HSP90/CDC37 promote AKT activity by stabilizing AKT. Activated AKT is involved in the regulation of many key molecules in cell growth and cell survival, including the IKK-IK-NFκB pathway, the stress-ASK-JNK pathway, the MDM2-p53 pathway, and many other proteins such as BAD and caspases-9.

AKT might change its conformation at this step followed by phosphorylation of AKT at Thr^{308} and Ser^{473}, which leads to the activation of AKT. The mechanism of AKT phosphorylation is still not completely understood. Among the protein kinases implicated in the phosphorylation of AKT are PDK1 (3'-phosphoinositide-dependent kinase) and MSK. While PI3K is the positive regulator for AKT activation, this process is negatively regulated by PTEN. PTEN is a lipid phosphatase that can dephosphorylate PtdIns(3,4,5)P3′ (phosphatidylinositol 3,4,5-trisphosphate). CTMP (Carboxy-terminal modulator protein, 27 kDa) is another negative regulator that can inhibit the phosphorylation of AKT at Ser^{473}. After being activated, AKT is dephosphorylated by phosphatases such as PP2A and its activity returns to basal level. ERK activation is also involved in AKT activation in some cell lines.

Deregulated PI3K-AKT signaling has been found in many cancer types, including glioblastoma, ovarian, breast, endometrial, hepatocellular, melanoma, digestive

tract, lung, renal-cell carcinoma, thyroid, lymphoid. The mechanisms involved in PH3K-AKT deregulated signaling include alterations in *PTEN* (mutations, allelic imbalance, inactivation), PI3K/p85α (mutation), PI3K/p110α (amplification), AKT (elevated kinase activity of AKT1, amplification and overexpression of AKT2), and RSK (amplification and overexpression). ERBB2 overexpression also leads to AKT activation and chemoresistance.

AKT might be involved in cell survival by multiple mechanisms, by phosphorylating and hence inactivating ASK1, BAD, caspase-9, and FKHR (a member of Forkhead family of TFs) (Fig. 13). BAD is a proapoptotic protein of the BCL-2 family (see Sec. 3.4.6). Phosphorylated BAD at serine^{136} by AKT or serine^{112} by RSKs can interact with 14-3-3 chaperone proteins and be sequestered from binding to BCL-XL, and thereby promoting cell survival. Phosphorylated FKHR cannot be translocated into the nucleus to activate its target genes of which some are proapoptotic proteins such as BIM and FAS ligand. AKT can also phosphorylate IKK (IκB kinase) and activate IKK-NFκB cell survival signaling. NFκB target genes include *IAP*s (c-*IAP*1, c-*IAP*2, and *XIAP*), and *GADD*45β. GADD45β overexpression can inhibit JNK activation, and XIAP can inhibit caspase activation. AKT can phosphorylate MDM2, which can translocate into the nucleus more efficiently and bind to p53, leading to E3 ubiquitin ligase-mediated degradation of p53. AKT promotes the transcriptional activity of ERα, independent of estrogen binding and resistant to tamoxifen.

3.4.3 Guanine Nucleotide Binding Proteins: G-Proteins

G-proteins can be divided into the heterotrimeric G-proteins and small G-proteins, both are regulated by GDP/GTP binding. The heterotrimeric G-proteins contain three subunits, and at least 16 different α-subunits, 4 β-subunits, and several γ-subunits have been identified. These G-proteins are distinguished by its α-subunit, which can be classified as Gs (stimulatory), Gi (inhibitory), Go, and Gq. Gs activates adenylyl cyclase, while Gi inhibits adenylyl cyclase, and Go is linked to the activation of ion channel. The α-subunit is about 40 kDa and it has the binding site for guanine nucleotide GTP/GDP, β- and γ-subunits are 37 kDa and 8 kDa respectively. In the inactive G-proteins, the α-subunit is bound to GDP and the three subunits form a tight complex. When the ligand binds to the receptor, GDP is dissociated from the α-subunit and GTP is recruited to bind the α-subunit. The GTP-bound α-subunit then dissociates from the β- and α-subunits, resulting in activation of G-proteins. The dissociated GTP-bound α-subunit may activate the adenylate cyclase to increase cAMP level, to activate PLCβ1 and PLCβ2, and to activate the RAS-RAF-MEK-MAPK pathway to promote cell proliferation (Fig. 14). The dissociated β- and α-subunit complex may activate PLCβ2. GTP hydrolysis is catalyzed by the intrinsic GTPase activity of the α-subunit. Examples of oncogenes related to this pathway include the Gq-protein α-subunit and PLCβ.

The RAS and RHO proteins are small G-proteins (small GDP/GTP binding proteins, 21-kDa) containing only one polypeptide. The activity of small G-proteins is determined by the ratio of GTP/GDP-bound forms in the cells, and the switch of these two forms is regulated by guanosine nucleotide exchange factors (GEFs), GTPase activating proteins (GAPs), and guanosine nucleotide dissociation inhibitor (GDIs). While GEFs promote GTP binding and activation of

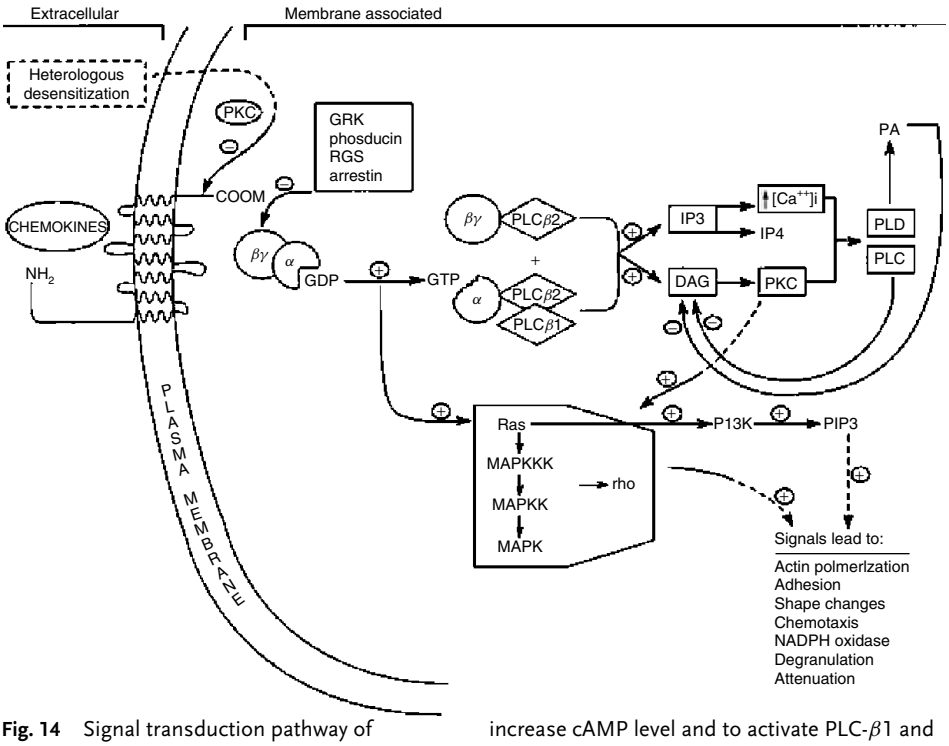

Fig. 14 Signal transduction pathway of G-protein-coupled receptors. The heterotrimeric G-protein-coupled receptors are seven-transmembrane protein receptors. Upon receptor activation by its ligand binding, the GTP-bound α-subunit dissociates from the β- and γ-subunits, resulting in activation of G-proteins. The dissociated GTP-bound α-subunit may activate the adenylate cyclase to increase cAMP level and to activate PLC-β1 and PLC-β2. The dissociated β- and α-subunit complex may activate PLCβ-2. RAS-RAF-MEK-MAPK pathway may also be regulated by activated G-proteins. (From Teresa Krakauer, Jan Vilcek, Joost J. Oppenheim. (2003). Fundamental Immunology, reprinted by permission of Lippincott Williams & Wilkins).

small G-proteins, GAPs inactivate small G-proteins by activating the intrinsic GTPase activity to hydrolyze GTP to GDP. In addition to SOS, as described above, the other GEFs for RAS activation include RASGRF1/2. RASGFP, CNRASGEF, and PLC-γ; and the GAPs for RAS inactivation include p120GAP, NF-1GAP, GAP1m, p135SYNGAP. RAS-mediated transformation involves RAF-MAPK pathway (see Sec. 3.4.1), but RAF activation is dispensable for RAS-mediated transformation in NIH 3T3 fibroblasts. This could be attributed to other RAS effector proteins that include PI3K, PLC-ε, RALGDS, RIN 1, AF-6, NORE1, and RASSF1. Activation of PI3K-AKT pathway by RAS may be mediated by interaction of p110 subunit with GTP-bound RAS.

The RHO family members are involved in cell invasion and motility and thus tumor metastasis. Cell migration and invasion involves dynamic changes in extracellular matrix, cell surface structures including focal adhesions, interaction with neighboring cells, and the intracellular motile machinery including actin stress fiber and myosin reorganization. A variety

of growth factors, motility factors, and extracellular matrix components have been shown to promote cell migration and invasion. The small GTPases of the RHO family have been shown to play pivotal roles in these signaling pathways, leading to metastasis. RHO-like GTPase family includes RHO (A, B, C), RAC (−1, 2, 3), CDC42 (CDC42Hs, G25K), and other members (RHO-6, 7, D, E, G, TC10, TTF). More than 30 GEFs and more than 20 GAPs that are involved in regulating RHO-like GTPases have been identified. Among the RHO-like family members, RHOA is upregulated in highly metastatic colon cancer, and overexpression of RHO C promotes cell motility and invasiveness in melanoma cells.

3.4.4 The JAK-STAT Signaling Pathway

JAK (Janus kinase) family proteins are associated with the receptors for interferons, cytokines, growth hormone, and the v-ABL oncoprotein. STATs are major effectors for JAK kinase–mediated signaling and gene expression. There are at least four members in the JAK kinase family, TYK2, JAK1, JAK2, and JAK3. Interferons have antitumor activities, and JAK family kinases are critical mediators for interferon-triggered signaling pathways. On the other hand, constitutive activation of JAKs and STATs are also involved in the malignant transformation of many types of cancers. In addition to STAT activation, other signaling pathways that may be activated by JAK include RAS-RAF-MEK-MAPK pathway, PI3K-AKT pathway, and activation of BCL-2 family members.

STATs (STAT 1–6) are transcription factors activated in response to cytokines as well as some growth factors. STATs function in transmitting signals from cell surface receptors to the cytoplasm and then translocating to the nucleus, where they act to regulate gene expression. STAT tyrosine phosphorylation is required for the biological function of STATs. This occurs when cytokines such as interleukin 6 (IL-6) and interferons or growth factors such as PDGF and EGF bind their respective receptors, which results in STAT protein recruitment to the inner surface of the plasma membrane in the vicinity of the cytoplasmic portion of the receptors. Tyrosine kinases that are known to phosphorylate STATs are non-RTKs such as SRC, JAK1, and JAK2. Several lines of evidence have implicated that some STAT family members, in particular, STAT3 and STAT5, are involved in malignant transformation and tumor cell survival. STAT3 involvement in oncogenesis is most thoroughly characterized. STAT3 is found constitutively tyrosine-phosphorylated (Y^{705}) and activated in many human cancers. This abnormal activation of STAT3 is prevalent in breast, lung, pancreatic, head and neck, brain, and prostate carcinomas. Recent studies have found that STAT3 is also constitutively activated in a significant fraction (74%) of malignant ovarian adenocarcinomas and ovarian cancer cell lines, but not in normal ovarian surface epithelial cells. Oncostatin M and IL-6, the JAK-STAT activators, have also been found to be overexpressed in ovarian cancer. Selective inhibition of JAK1/2, with a tyrphostin known as AG490, leads to enhanced apoptosis induced by cisplatin in ovarian cancer cells. Inhibition of STAT3 using antisense oligonucleotides and dominant negative STAT3 significantly suppresses the growth of ovarian cancer cells harboring constitutively active STAT3. Recently, Blaskovich and colleagues identified a small molecule from the National Cancer Institute Diversity Set that disrupts aberrant STAT3 signaling. This compound, JSI-124 or Cucurbitacin I, rapidly suppresses the levels

of phosphorylated STAT3 in SRC transformed cells. Future studies are likely to assess the therapeutic efficacy of this agent in a number of cancers that express constitutively active STAT3.

3.4.5 Other Protein Serine-threonine Kinases

3.4.5.A **PKC (Protein kinase C)** PKC belongs to the AGC family, which includes PKA, PKB/AKT, PKC, and RSKs. There are at least 10 members in the PKC family, the classical PKCs include PKC-α, PKC-β1, PKC-β2, and PKC-γ; the nonclassical PKCs include PKC-δ, PKC-ε, PKC-η, and PKC-θ; and atypical PKCs include PKC-ζ and PKC-λ. The classical PKCs require both DAG and Ca2+ for activation, while nonclassical PKCs only require DAG for activation. DAG and Ca2+ can be produced by PLCs that can be activated by G-proteins or RTKs. In addition, PKC is also activated by the tumor-promoting phorbol esters. Some of the PKC members, including PKC-β1, PKC-γ, PKC-ε, and PKC-ζ have been identified as being oncogenic.

3.4.5.B **MOS** MOS expression is restricted to germ cells and may be involved in meiotic cell cycle. MOS protein does not contain a regulatory region and may be active constitutively, thus abnormal overexpression of MOS is a very potent oncogene. Targets of MOS include MAPK, which may account for its transforming activity.

3.4.6 Antiapoptotic Proteins

3.4.6.A **BCL-2 protein family and oncogenesis** As described above (see Sec. 2.2), senescent or damaged cells have to be cleared to maintain tissue homeostasis, and mitochondria-mediated apoptosis is a major apoptotic mechanism. In response to environmental stress and genomic DNA damage signals, release of cytochrome C and SMAC from the mitochondria into the cytoplasm is essential for the execution of the caspase-mediated apoptotic processes. The BCL-2 family members function as gatekeepers for the exit of cytochrome C and SMAC, and therefore are key regulators for cell life or death. Some of the BCL-2 family proteins are antiapoptotic and oncogenic, while others are proapoptotic and suppression of their function might be oncogenic. The biochemical mechanism by which BCL-2 family members control cytochrome C release is not completely understood.

BCL-2 was cloned because of t(14;18) chromosome translocation in B lymphoma, which results in BCL-2 overexpression and therefore inhibition of apoptosis. Members of the BCL-2 family may possess up to four conserved α-helical domains, designated BH1, BH2, BH3, and BH4 (BH represents BCL-2 homology). The mammalian antiapoptotic BCL-2 family members (including BCL-2, BCL-X_L, BCL-W, MCL-1, A1/BFL-1, BOO/DIVA, and NR-13) possess all four BH domains, and they are found in the outer mitochondrial membrane, endoplasmic reticulum, or outer nuclear membrane. Aberrant activations of these proteins are oncogenic. Proapoptotic BCL-2 family members could be multidomain proteins (including BAX, BAK, and BOK/MTD) or BH3-only proteins (including BID, BAD, BIK/NBK, BLK, HRK, BIM/BOD, BNIP3, NIX, NOXA). Many of the proapoptotic molecules, especially the ''BH3 domain only'' members are localized to the cytosol or cytoskeleton and undergo posttranslational modification after a death signal, which allows them to

target and integrate into the mitochondrial membrane to initiate mitochondrial dysfunction. For example, BAD becomes dephosphorylated after death stimulus, resulting in the interaction of the BH3 domain of active BAD with the hydrophobic pocket of BCL-XL at the mitochondrial membrane. RSK and AKT can inactivate BAD by phosphorylating BAD at ser^{112} and ser^{136} to promote cell survival. Double knockout, but not single knockout, of BAK and BAX are resistant to apoptosis, suggesting that BAK and BAX might be the intermediate step essential for mitochondrial dysfunction.

3.4.6.B **Inhibitors of apoptosis protein (IAP) family** The IAP (inhibitors of apoptosis protein) proteins include c-IAP1, c-IAP2, XIAP, and survivin. They can inhibit the activation of caspases and apoptosis, and, therefore, may promote tumorigenesis when abnormally activated. The conserved BIR (baculovirus IAP repeat) domain of IAPs is involved in the antiapoptotic activity of IAPs. Survivin is expressed in almost all tumor types and it is involved in both antiapoptosis and cell cycle.

3.4.7 Chaperone Proteins

Heat-shock proteins (HSPs) are induced by environmental stress that might be involved in protein folding, stability, and degradation. They might be involved in tumorigenesis by affecting their client proteins, such as AKT, HER-2, and KIT, that are involved in cell survival or apoptosis. HSP90 has been shown to promote AKT activation by stabilizing AKT.

JNK is a MAPK activated by stress signals (e.g. UV, heat shock, osmotic shock, starvation) that initiate the mitochondrial protein release resulting in apoptosis. Proteins that inhibit JNK activation might be oncogenic, and these proteins include HSPs, JNK interacting proteins (JIPs), GST, EVI, and γ-synuclein. γ-Synuclein, also termed breast cancer–specific gene 1 (*BCSG1*), is aberrantly expressed in the vast majority (70%) of late-stage breast and ovarian cancers. Pan and colleagues have shown that γ-synuclein may promote cell survival and inhibit stress-induced and chemotherapeutic drug–induced apoptosis by suppressing JNK activation and promoting ERK activation. AKT is also activated by γ-synuclein and is involved in suppression of JNK activation and inhibition of apoptosis. The inhibition on JNK activation could be executed at different levels of JNK signaling pathway. JIPs could interact with upstream kinases, including upstream MKK7, MLK, RHO/GEF, and JNK phosphatase MKP-7. GSTs may function as suppressors to keep the JNK basal activity at a low level. JIP-1 can bind to JNK and block its translocation from cytoplasm into nucleus to activate its nuclear substrate such as c-JUN and ATF; EVI-1 is a transcription factor that blocks JNK function in the nucleus.

3.4.8 Oncogenes Associated with Cancer Cell Adhesion and Motility

One feature of cancer cells is anchorage-independent growth, and genetic or epigenetic alterations of oncoproteins involved in integrin and cadherin initiated signal transductions play significant roles in these processes. These include FAK, SRC, ABL, the small G-protein RHO families, as well as the MAPK and PI3K-AKT pathways. The other pathways include CAS/CRK and the low M(r) protein-tyrosine phosphatase (PTP). Cell migration and invasion involves dynamic changes in extracellular matrix, cell

surface structures, including focal adhesions, interaction with neighboring cells, and the intracellular motile machinery including actin stress fiber and myosin reorganization. The small GTPases of the RHO family have been shown to play pivotal roles in these signal transduction pathways leading to metastasis.

3.5 Transcription Factors and Nuclear Oncogenes

3.5.1 *FOS* and *JUN* Families

JUN family members include c-*JUN*, *JUN*-B, and *JUN*-D. *FOS* family members include c-*FOS*, *FOS*-B, *FRA*-1, and *FRA*-2. JUN family members and the FOS family members form the AP-1 transcription factor. Target genes of AP-1 include growth factors and phorbol ester inducible genes that are involved in cell proliferation and transformation. These target genes in turn can activate JUN and FOS by signaling cascades. FOS and JUN may become oncogenic by overexpression or alteration in protein structure.

3.5.2 c-*MYC*

There are three members identified in the *MYC* family, c-*MYC*, N-*MYC*, and L-*MYC*. N-*MYC* was originally identified in neuroblastoma cells. c-*MYC* is one of the immediate-early responsive genes, it is induced rapidly in the G_1-phase, and its expression is maintained at high levels throughout the cell cycle. Instead of forming homodimers, MYC form heterodimers with MAX to bind to DNA sequences and activate the transcription of MYC-target genes. In addition to forming MYC-MAX heterodimers, MAX can form MAX-MAX homodimers or MAX-MAD heterodimers. MAX-MAX or MAX-MAD dimers recognize the same sequence for binding (the E-box, with the consensus sequence of $CA^T/_CGTG$) as MYC-MAX, but function as repressors of transcription. Mechanisms of MYC activation include overexpression, gene amplification, and mutation. Different MYC members have been associated with many different cancer types. MYC may have synergistic role with Ha-RAS in tumorigenesis, as evidenced by tumor formation of rat embryo fibroblasts transfected with both Ha-RAS and MYC, but not transfected with Ha-RAS alone.

3.5.3 *REL* Oncogene: the NFκB Family Proteins

The *REL* oncogene belongs to The *NFκB* family, which includes *NF-κB*1 (p105/p50), *NF-κB*2 (p100/p52), *REL*, *RELA* (p65), and *RELB*. While mature NF-κB proteins are derived from their precursor proteins by proteolytic cleavage, the REL proteins are not posttranslationally processed. The REL/NF-κB proteins have a conserved N-terminal region for DNA binding and dimerization, and they can form homo- or heterodimers. Usually REL/NF-κB dimers are associated with an inhibitory subunit (IκB) that retains them in the cytoplasm. When cells are stimulated and the IKKs (IκB kinases) are activated, IKKs phosphorylate IκB, resulting in dissociation of REL/NF-κB from IκB and translocation of REL/NF-κB into the nucleus. In the nucleus, REL/NF-κB bind to the REL/NF-κB consensus sequences and activate the transcription of the target genes. The upstream kinases for IKKs phosphorylation include the AGC kinase such as PKB/AKT, PKC, and RSK1. The target genes of NFκB that are involved in cell survival include IAP proteins (c-IAP1, c-IAP2, and XIAP), and GADD45β. GADD45β overexpression can inhibit JNK activation, and XIAP (X-linked inhibitor of apoptosis) can inhibit caspase activation.

3.5.4 Estrogen Receptor and Other Steroid Hormone Receptors

The receptors for steroid hormones (e.g. estrogen, progesterone, glucocorticoids, and testosterone) are located in the cytoplasm, and are translocated into the nucleus when bound by the steroid hormones. The expression of the target genes of steroid hormone receptors may account for the oncogenic potential of these receptors. The receptors for steroid-related hormones, such as thyroid hormones and retinoid acids, may also be converted to oncogenes. Examples include the *ERBA* gene, which encodes the receptor for the thyroid hormone.

The great majority (80–90%) of ERs (estrogen receptor) are in the cytoplasm and nucleus. ER can either be activated by the binding of its ligand estrogen or by phosphorylation of ERα/ser^{167} by AKT or RSK1. Hence, there are two functions of ER, the estrogen-independent activation function 1 (AF-1) and the estrogen-dependent activation function 2 (AF-2). ERs mediate most of the biological effects by binding to estrogen response elements in the promoter region of target genes, and inhibition of ER by antiestrogen such as tamoxifen inhibits the growth of ER-positive breast cancers by reducing the expression of estrogen-regulated genes. The target genes of ERs include *BCL-2, EGFR, ERBB2*, macrophage inhibitory cytokine 1, *PR* (progesterone receptor), and *pS2*.

Although a great majority of ERs are in the cytoplasm and nucleus, a small fraction of ERs are present in cell surface and are involved in the nongenomic effect of ER. In ER-positive MCF-7 cells, estradiol (17-βE2) can rapidly ($\leq$10 min) activate AKT1 via ERBB2; this effect is dependent on ER and can be abrogated by the PI3K inhibitor or 4-hydroxytamoxifen. The activated ER/ERBB2 may lead to rapid phosphorylation of SHC and SHC/GRB2/SOS complex formation, as well as MAPK activation in MCF-7 cells. The nongenomic effect of ER could be mediated by the activation of PI3K-AKT and MAPK pathways.

3.5.5 Homeodomain-containing Proteins

Homeodomain-containing genes or *HOX* genes are transcription factors that are key regulators of cell proliferation and apoptosis for pattern formation in embryogenesis. These genes have a conserved homeodomain that can bind DNA sequences with a TAAT core site. Abnormal expression of some homeodomain-containing genes may contribute to tumorigenesis by deregulating cell proliferation and apoptosis.

3.5.6 *MYB* Family

The *MYB* family genes include v-*MYB*, c-*MYB*, A-*MYB*, and B-*MYB*. MYB family members are transcription factors that bind to DNA sequences (PyAACG/TG) as a monomer and are involved in the regulation of proliferation and differentiation of many different cell types. Deletion at either the N- or C-terminal has been found to convert MYB to its oncogene form. Oncogenic activation of c-MYB may be involved in malignant transformation of hematopoietic cells.

3.5.7 *ETS* Gene Family

The *ETS* family have at least 12 members, including *ETS*-1, *ETS*-2, *FLI*-1, *SPI*-1, *ERG*, and *ELK*-1. These genes may become oncogenic via viral integration, chromosomal translocation, or integration into the viral genome. ELK-1 is a target of the MAPK and activated ELK-1 is involved in the expression of the immediate-early gene expression. ETS-1 and ETS-2 can be activated

by growth factors and phorbol esters and the activated ETS-1/2 can cooperate with AP-1 (FOS/JUN) to regulate expression of target genes.

4 Identification of Oncogenes

As described above (see Sec. 2.1.), identification of oncogenes from transforming viruses plays an immeasurable role in the early days of cancer research and contributes significantly to the identification of many important oncogenes. Although very powerful, this approach is very limited because of the nature of methodology. The neoplastic properties of oncogenes are usually gain of function, and those of tumor suppressor genes are of loss of function. Therefore, approaches to identify differentially expressed genes between tumor cells and normal cells have been attempted, and several of these approaches arose along the way. These include the various differential gene expression display approaches, SAGE (serial analysis of gene expression), and DNA microarray. In the protein level, tissue-array and proteomics are in the development for the application of oncogene identification and validation. Genomic DNA transfer initially and gene transfer later into appropriate cell lines or in transgenic mice have been widely used to validate the oncogenic potentials of candidate oncogenes.

5 Oncogenes and Clinical Implications

5.1 Oncogenes and Cancer Diagnosis and Prognosis

Abnormal expression and/or activation of many of the oncogenes are important diagnostic biomarkers for cancer diagnosis and prognosis. Many of the oncogenes described in this review are applied for the diagnosis and prognosis of many different cancer types.

5.2 Oncogenes and Cancer Therapy

The most frequently used approaches in the current regimens for cancer therapy include surgery, radiotherapy, and chemotherapy. Although significant progress has been made in cancer therapy, cancer has been the second leading cause of death, second only to heart disease in the United States for many years. Therefore, better/improved diagnosis and therapy approaches are needed for the treatment and/or cure of cancer. Oncogene-based therapies have been and will continue to play a significant role in this respective. Below we will briefly discuss the potential of oncogene-targeted chemotherapy and immunotherapy.

5.2.1 Oncogene-Targeted Chemotherapy

The main targets of conventional chemotherapeutic drugs are microtubules and genomic DNA, these include the microtubule-interfering agents (e.g. vincristine, vinblastine, vinorelbine, paclitaxel, docetaxel), DNA-damaging agents such as topoisomerase inhibitors (e.g. etoposide, doxorubicin, irinotecan, and topotecan), alkylating agents (e.g. cisplatin, cyclophosphamide and ifosfamide), and some antimetabolites (e.g. gemcitabine). These agents kill the cells, cancer cells as well as normal cells, by activating the apoptotic pathways. As described in this review, the apoptotic pathways can be modified or overridden at many steps by oncogenes involved in the antiapoptotic or cell survival pathways.

Blocking the activity of one or multiple oncogenes could either sensitize cancer cells to conventional chemotherapy drugs, or kill the cancer cells by themselves.

Those potential therapeutic targets include the cell cycle regulatory proteins such as CDKs, receptor tyrosine kinases such as EGFR and HER-2/neu, farnesylated proteins such as RAS, nonreceptor cytosolic kinases such as RAF, MEK, PI3K, and AKT, nuclear oncoproteins such as MYC and ER. Among those, Tamoxifen against ER, and small-molecule EGFR tyrosine kinase inhibitors (EGFR-TKIs), such as ZD1839 (Iressa™) and OSI-774, are now in the clinic. The latter inhibit ATP binding to the tyrosine kinase domain of the receptor, thereby inhibiting tyrosine kinase activity and autophosphorylation, and subsequently blocking signal transduction from the EGFR.

The oncogene-based therapy that has garnished the most attention is imatinib mesylate (IM) (Gleevec™, STI-571). Imatinib mesylate is an oral 2-phenylaminopyrimidine derivative that acts as a selective inhibitor of the ABL, KIT, and PDGFR tyrosine kinases. Imatinib mesylate also inhibits the causative molecular translocation in CML, BCR-ABL. *In vitro* imatinib mesylate inhibits SLF-dependent human KIT expressing myeloid leukemia cell line and an SLF independent mast cell leukemia cell line, which expresses an activating juxtamembrane V560G mutation of c-KIT. In preclinical studies, imatinib has been shown to inhibit the activity of c-ABL, BCR-ABL, and PDGFRA/B. Several phase I/II clinical trials have demonstrated the efficacy of imatinib in the treatment of CML patients with the BCR-ABL translocation. Patients who progressed on interferon-α were not only shown to have clinical responses to IM, but some patients also demonstrated cytogenetic complete remissions. Current trials are evaluating the role of imatinib mesylate with chemotherapy.

Imatinib mesylate has also been shown to be a specific *in vitro* inhibitor of c-KIT phosphorylation in several tumor cell lines. It can rapidly inhibit c-KIT phosphorylation and tumor cell proliferation, without inducing apoptosis, in a human GIST cell line. The c-KIT target has been successfully exploited in phase I–III clinical trials of imatinib mesylate (STI571, Gleevec).

5.2.2 Oncogene-targeted Immunotherapy

Monoclonal antibody therapy targeted against a variety of epitopes, including oncogenes, has emerged as an important therapeutic modality for cancer. Antibodies may exert antitumor effects by inducing apoptosis, interfering with ligand–receptor interactions, or preventing the expression of proteins that are critical to the neoplastic phenotype. In addition, antibodies have been developed that target components of the tumor microenvironment, perturbing vital structures such as the formation of tumor-associated vasculature. Some antibodies target receptors whose ligands are growth factors, such as the EGF receptor. As indicated above, EGFR is overexpressed in many cancers, and therefore has prompted the development of a variety of agents targeted to the extracellular ligand-binding domain, the intracellular tyrosine kinase domain, the ligand, or to synthesis of the EGFR. These agents are being investigated as monotherapy as well as in combination with conventional therapies.

A number of monoclonal antibodies directed against the extracellular ligand-binding domain, which is thought to prevent ligand binding (e.g. IMC-C225

and ABX-EGF), have been developed. Another approach is provided by bispecific antibodies (e.g. MDX-447) that target the extracellular ligand-binding domain of the EGFR as well as epitopes on the surface of immune effector cells such as macrophage-activated killer cells. The aim is to encourage immune effector cell recruitment at the site of tumors, and hence, initiate destruction of the tumor cells and then stimulation of additional immune responses. Single-chain fragment variable (scFv) antibodies against the EGFR conjugated to toxins, such as pseudomonas endotoxin A (ETA), as well as to fungal and plant-derived toxins, have also been investigated. One of the most potent conjugates is the scFV-14e1-ETA-fusion toxin, which binds to EGFR and the mutant form, EGFRvIII, with equal affinity, but has 100-fold enhanced cytotoxicity against tumors expressing EGFRvIII compared to those expressing EGFR.

The most advanced anti-EGFR mAb in clinical development is cetuximab. Cetuximab is a genetically engineered chimeric antibody, which has been shown to block *in vitro* phosphorylation of the EGFR and induce receptor internalization, as occurs with binding of the natural ligand. This results in inhibition of cell growth and survival. It causes an increase in the expression of the cell cycle inhibitor $p27^{KIP1}$, resulting in the formation of inhibitory $p27^{KIP1}$-CDK2 complexes that prevent cells from exiting the G_1-phase of the cell cycle. Cetuximab has also been shown to induce apoptosis in some cell lines and to inhibit the production of angiogenic factors, *in vitro* and *in vivo*, as well as metastasis. Preclinical studies have also demonstrated that cetuximab can enhance the effects of cytotoxic agents and radiotherapy, for example, cetuximab, in combination with topotecan or irinotecan, increased survival of nude mice bearing human colon cancer xenografts. In recent clinical trials, cetuximab has shown promise in several solid tumors that express EGFR. For example, patients with cisplatin-resistant head and neck or colorectal cancers appear to respond upon subsequent treatment with cisplatin and cetuximab. The most common adverse event related to Cetuximab was acniform rash.

The most successful antibody therapy for solid tumors is trastuzumab, also known as Herceptin and rhuMab HER2. HER-2/neu (c-ERBB2) is a member of the EGF receptor family, has been targeted for therapy because it is overexpressed in ~25% of breast cancers, as well as other adenocarcinomas of the ovary, prostate, lung, and gastrointestinal tract. Trastuzumab is a humanized antibody derived from 4D5, a murine mAb, which recognizes an epitope on the extracellular domain of HER2/Neu. On the basis of a series of clinical trials, trastuzumab was approved by the FDA to treat women with metastatic breast cancer with HER2/neu overexpression, given either alone or in combination with paclitaxel. Herceptin also has activity in combination with vinorelbine, docetaxel, cisplatin, and the combination of gemcitabine and paclitaxel. The use of Herceptin for breast cancer is considered a therapeutic success. Although other adenocarcinomas may overexpress HER2/Neu, clinical trials have not documented consistent therapeutic successes in other cancers. Therapeutic antibodies have made the transition from concept to clinical reality over the past two decades. Many are now being tested as adjuvant or first-line therapies to assess their efficacy in improving or prolonging survival. Although new tumor-specific antigens are

being explored, oncogenes have proven to be the most effective molecular targets for therapy.

6 Perspectives

Carcinogenesis is a multistep process that involves alterations in many specific genes. The normal cell has multiple independent mechanisms that regulate its growth and differentiation and several separate events are required to override these control mechanisms. The fundamental mechanisms underlying the genetic basis of cancer are constantly being defined and involve alterations in proto-oncogenes, tumor suppressor genes, and mismatch repair (MMR) (also known as DNA repair genes, or ''caretaker'' genes). Malignancy appears, when these genes suffer regulatory perturbations and special types of mutational damage that can disrupt this balance, thus altering normal development and differentiation. However, the combination of changes both necessary and sufficient to induce malignant transformation varies greatly from tumor to tumor and from individual to individual. This type of heterogeneity is primarily the basis for the generally poor success rate in effectively treating most types of cancer. Because oncogenes are normally upregulated and constitutively activated in cancers, as opposed to tumor suppressors or *MMR* genes, they have become the primary target for the development of novel antitumor therapies. Current clinical trials with molecular targeted agents such as Herceptin and Gleevec give hope that by better understanding the role of oncogenes in the pathogenesis of cancer, a cure for many forms of the disease may not be that far behind.

chromatin by a number of Caspase-dependent or Caspase-independent biochemical events.

Binary State (of Regulatory Molecules)
Most, if not all, biochemical regulatory proteins can be present at any one time in an ''on'' or an ''off'' molecular form, with regard to one or more of their functions.

Carcinogenesis
This is now recognized to be a progressive, usually rather slow, multistep process involving sequential mutations, failure of adequate DNA repair, activation of oncogenes, loss of tumor suppressor function, epigenetic changes, and a gradual (or less frequently, rapid) transition from benign to malignant phenotypes.

Cellular Adhesion
Downregulation of 'adherens junctions' (AJ) assembly by mutations, hypermethylation, or transcriptional repression of the adhesion molecule E-Cadherin, has been described in several malignancies, and particularly in human diffuse gastric carcinomas, lobular breast cancers and familial gastric cancers. In many ways, E-cadherin behaves as a tumor suppressor gene, while beta-catenin behaves as a potentially potent oncogene.

Cell Cycle Checkpoints
Mammalian cells can remain quiescent (in Go phase of their cell cycle) for long periods of time, but the right combination of growth factors can induce them to enter G1 and then, if no impediment occurs, progress through S-phase (DNA replication), G2, and mitosis, and complete their cell division.

Chemoprevention
The treatment of carcinogenesis, its prevention, inhibition or reversal.

Drug Resistance
Surprisingly, conventional chemotherapy and radiotherapy work not because cancer cells are especially more ''sensitive'' to their cytotoxic effects than normal cells, but because normal cells can usually recover faster and more efficiently than cancer cells. Normal tissues virtually never develop resistance to chemotherapy, but human cancers are frequently chemo- or radio-resistant when they are diagnosed, or can become resistant following cytotoxic treatments, because of multiple pharmacological, cell kinetic or molecular mechanisms.

Growth Factors
They were defined in the 1970s, long before their molecular characterization and purification, as *substances other than nutrients required by cells in vitro for their survival, proliferation, and differentiation.*

Intraepithelial Neoplasia
Intraepithelial neoplasia (IEN) is a moderate to severe dysplasia that occurs on the carcinogenic pathway from normal tissue to malignant cancer.

Oncogenes
These are growth control genes present in the human genome (as ''proto-oncogenes''), as well as in the genomes of most, if not all, multicellular organisms. Incorrect expression or mutation of an oncogene usually results in ''Gain of Function'' and unregulated cell growth, as seen in malignant cells.

Mutations
The molecular changes in DNA associated with carcinogenesis are not very different from those associated with genetic variation and molecular evolution of organisms and species. These changes include local changes in DNA sequences, rearrangement of DNA segments within the genome, and (in the case of viral carcinogenesis) horizontal transfer of a DNA (or RNA) segment originating in another kind of organism.

Proteasomes
The average human cell contains about 30 000 proteasomes, each of which contains several protein-digesting proteases. Among other functions, they control the intracellular half-life of important regulatory proteins.

Stromal cells and Cancer
Stromal cells are all cells in a tumor that are not the cancer cells.

Tumor Antigens
These are molecules that contain the epitope determinants recognized by T cells that specifically target tumor cells.

Tumor Suppressor Genes
Unlike oncogenes, tumor suppressor genes (formerly ''antioncogenes'') display the function of suppressing cellular proliferation, and/or maintaining cellular differentiation, facilitating normal cellular adhesion mechanisms, stopping entry into the cell cycle (G1, S-phase, mitosis or G2) to allow DNA-repair mechanisms, maintaining normal cellular shape and cell contact inhibition mechanisms, and promoting normal differentiation and senescence.

Molecular Oncology can be defined as *that branch of medical science that looks at the cancer problem from a molecular point of view*. For several reasons, ''molecular oncology'' represents ''the heart of the matter'' of cancer.

As it would be quite an ambitious, and virtually impossible, task to pretend to cover the whole subject of ''Molecular Oncology'' in a single unipersonal review, what follows is a short personal view of what the author regards as the basic molecular understanding of cancer in the year 2004, and the more likely therapeutic implications of this new molecular knowledge.

We should not forget the huge prevalence of malignant diseases in the developed world. Cancers are probably responsible for one-third of deaths in men in industrialized countries and for almost one-fourth in women. At the beginning

of the twenty-first century, these diseases still cause a lot of human suffering, despite very significant progress in their early detection, improvements in radical treatments (local or systemic), and better medical control of iatrogenic side effects of chemotherapies.

In the same way as the invention and later refinement of the microscope eventually led to the discovery and classification of pathological microorganisms, the discovery of DNA, RNA, proteins, proteoglycans and other regulatory molecules (including lipids, arachidonic acid derivatives, steroids, and sex hormones) is rapidly leading to a better and deeper understanding of cancer, and remains the best promise to lead to better and more effective methods for cancer prevention, early detection, prognostic classifications, and cure.

This is because it is currently believed that cancer can be truly understood in terms of those molecular changes, genetic and epigenetic, that gradually lead a given cell clone, within a given tissue field, to develop a certain ''competitive advantage'' over neighboring cell clones, enabling the transformed cell clone to gradually displace its neighbors and grow into a neoplastic tissue. Finally, this ''new tissue'' can go on to transform itself into a malignant neoplasia, leading to invasion of local organs, or distant spread (generally through the bloodstream, the lymphatic system, or both). The growth of cancer cells at distant sites is called *metastasis*.

''Cancer'' is a state, whereas ''carcinogenesis'' is a process. Key to the multistep genetic nature of cancer is that carcinogenesis is ''progressive.'' In most epithelial tissues, progression means the sequential accumulation of somatic mutations, or even epigenetic changes (like abnormal DNA methylation patterns). In some cases of familial predisposition to cancer, some of these mutations are inherited.

Gradually, a given target tissue experiences a transition from normal histology, to proliferative and/or dysplastic changes, to so-called *intraepithelial neoplasia* (*IEN*), which can be early or severe, to superficial cancers *(in situ)*, and finally to invasive disease. In some instances, this process of malignant transformation may be aggressive and relatively rapid (e.g. in the presence of a DNA repair-deficient genotype, or an aggressive oncogenic virus, or a lethal combination of ''oncogenic hits''), but in general these changes occur over a long period of time, like 3 to 30 years.

The problem is that in the past two and a half decades there has been an ''explosion'' of information, rather than true knowledge, about the molecular aspects of cancer. More than 300 different genes and their respective protein products have been described as being directly or indirectly linked to cancer. The number of such 'cancer-related genes' is constantly increasing and the final figure could well be more than 1000. Although it seems reasonable to believe that some, or many, of these 'cancer-related' genes may represent the *consequence* rather than the *cause* of the cellular development of the cancer cell phenotype, the 'trees' are so many that there is a real risk of missing the ''wood.''

Indeed, some believe that, in the not too distant future, relevant information will pass from the Molecular Pathology Laboratory to the busy Cancer Clinical Units only with the help of clever computer programs. Before clinicians can make up their minds about the curability or incurability of any given cancer, and in order to decide which sequence and combination of drugs to use to treat a particular patient, they

will have to consult a computer program and the Molecular Pathology Laboratory. Although there is still no treatment for any of the major lethal cancers that is as effective as, say, antibiotics are against infections, there is vast accumulated knowledge of the fine regulatory mechanisms that are deranged in cancer cells, and this undoubtedly promises new therapeutic insights. For example, selective oral tyrosine-kinase inhibitors (Gleevec), for chronic myeloid leukemia, and specific monoclonal antibodies (Herceptin) for breast cancer or some lymphomas (Mabthera), have been introduced into routine clinical use.

In contrast to the situation twenty years ago, not only do we now know of many molecular targets to design new drugs for the chemoprevention or treatment of cancer but, paradoxically, we have an apparent excess of targets for our current resources of drug development worldwide. The Human Genome Project has completed its first basic human genome map well ahead of schedule, and it is likely to give us further insights and more potential targets. It is now estimated that the human genome contains some 35 000 genes, which is less than had originally been estimated by most researchers. Many of these genes are well characterized and their functions in various pathways are known. But the real function of the majority of these human genes remains inconclusive. In other words, the rate-limiting step in true progress against cancer is the amount of resources we can spend, and the optimization and coordination of this huge research process, rather than a shortage or lack of therapeutic targets.

Selecting the right targets for cancer therapy can make a big difference. If, for example, we were clever or lucky enough to correctly guess the right targets for the main human cancers, and if large multinational pharmaceutical companies agreed to focus their efforts and enormous resources on these right targets, then revolutionary new cancer treatments might become available for clinical testing within 5 to 10 years. But, if we got it wrong, or not enough importance was given to this war against cancer by politicians or business people, then it might take another 20 or 30 years, or even more.

1
The Molecular and Clonal Evolution of a Cancer

In view of the fact that the incidence of most of the common epithelial cancers is age related, the British epidemiologists Armitage and Doll had already calculated, in 1958, that for some of the common solid tumors the logarithm of cancer incidence should be linearly related to the logarithm of a person's age. If such an interpretation holds good, then we could deduce, from the slope of the death rate from cancer of the large intestine in relation to age (plotted logarithmically), that about 6 mutations are needed to produce a cancer of the large intestine.

This guess is extraordinary if one thinks that more or less the same conclusion was reached, based on molecular genetic knowledge, by the American scientists Fearon and Vogelstein in their classic work on colorectal tumorigenesis. The

'multistep mutations' theory of cancer was also supported by epidemiological evidence, and by the 'initiation and promotion' models of carcinogenesis. A characteristic feature of most forms of carcinogenesis is the long period that elapses between initial application of the carcinogen and the time the first cancers appear. It is necessary to apply coal tar repeatedly to the skin of a mouse for several months before any tumors are detectable. Similarly, most common human cancers can take 3 to 30 years or more to develop.

The chemical carcinogenesis experimental models also helped to identify at least two classes of carcinogenic compounds: the initiators and the promoters. For example, if a group of mice are fed a small amount of the carcinogen dimethylbenzanthracene (DMBA), this produces widespread irreversible alterations (presumably mutations) in the cells of each mouse. Subsequent irritation of the skin by painting it twice a week with croton oil (the ''promoter'') eventually results in the local appearance of tumors. These tumors will appear even if croton oil is not started until 16 weeks after the DMBA feeding, but no tumors arise if either DMBA or croton oil is given alone or if the order of the treatments is reversed. In several aspects, estrogens (in the case of breast cancer) and testosterone (in the case of prostate cancer) have also been regarded as potential tumor promoters.

Other insights into the ''genetic'' nature of tumorigenesis came from studies on viral carcinogenesis, and from seminal observations in the uncommon retinal cancers in children.

The discovery of tumor oncogenes and tumor suppressor genes almost twenty years ago opened the way to the study of the molecular epidemiology of cancer. It soon became apparent that in general more than one somatic mutational event is needed for malignant transformation, the possible exception being the uncommon hereditary retinoblastomas, already described by the ''two-hits model'' proposed by Knudson.

Later, it was found that certain carcinogens are linked to selective (though not entirely ''specific'') mutational events. For example, researchers have described molecular linkages between exposure to carcinogens and cancer types, in p53 mutational spectra of hepatocellular carcinoma, skin cancers, and lung cancer. In 1990, Fearon and Vogelstein proposed a molecular model for colorectal carcinogenesis, based on the sequential accumulation of genetic events in key regulatory genes along the sequence from adenoma to carcinoma.

More recently, in 1997, Kinzler and Vogelstein proposed the concept of two different types of carcinogenic genetic events: those involving ''gatekeeper'' genes, characterized by their control of net cellular proliferation, and those involving ''caretaker'' genes, associated with maintenance of genomic integrity. Examples of gatekeeper genes include APC and beta-catenin in colon epithelium, Rb in retinal epithelial cells, NF1 in Schwann cells, and VHL in kidney cells. Thus, it is proposed that an alteration in APC leads to a derangement of the cellular proliferation pathway that is important for maintaining a constant cell population, at least in colonic cells. The identification of other gatekeeper genes is anticipated, and some may be genes crucial to morphogenetic events of specific tissues. Unlike gatekeeper genes, caretaker genes generally maintain genomic stability and are not involved directly in the initiation of the neoplastic process, but their mutations enhance the probability of mutations in

other genes, including those in the gatekeeper class. Because multiple mutations are found in cancer cells, the existence of a ''mutator phenotype'' was suggested by Loeb in 1991 as being an important step in tumor development. Candidate mutator genes are involved in multiple cellular functions needed for maintaining genetic stability, such as DNA repair, DNA replication, chromosomal segregation, cell cycle control, and apoptosis.

Some individuals may be predisposed to cancer because of inherited mutations of some key genes. This has attracted considerable attention in recent times, particularly in relationship to genes having susceptibility for breast cancer and colon cancer.

The genetic alterations in oncogenes generally lead to an increased function of the protein, whereas, in general, tumor suppressor genes are inactivated during carcinogenesis with apparent loss-of-function of the protein. However, the mechanisms of activation or inactivation are multiple, and their precise effects on gain- or loss-of-function are incompletely understood. *K-ras* and *H-ras* genes are examples of oncogenes that are preferentially altered by point mutation (codons 12, 13 and 61), generating a protein with constant GTPase activity. The *c-myc* gene can be activated by chromosomal translocation (in some leukemias) or by gene amplification (in some solid tumors). The *p53* and *Rb* tumor suppressor genes are often knocked out by point mutation in one allele and by deletion (loss of heterozygosity) at the other. Others, like *p16*, have high rates of homozygous deletions or promoter hypermethylation. Some genetic defects are fairly characteristic for a given tissue type (most colorectal cancers have APC or beta-catenin mutations). But the ''same players'' are frequently involved in different tumors. Each human cancer can be regarded as a different molecular entity, with a different matrix of molecular targets, and it evolves with time (even as a result of systemic or local therapies).

However, it would be a mistake to believe that all common epithelial human cancers follow these clear-cut histological sequential patterns from adenoma to carcinoma. In fact, only a minority of the commonest type of breast cancers (infiltrating ductal carcinomas, or IDC) arise from ductal carcinoma *in situ*. Thus, the molecular changes leading to IDC, accounting for almost 70% of all breast cancers, can happen before the histological features associated with DCIS become evident. DCIS is characterized by a proliferation of malignant epithelial cells confined to the mammary ducts without light microscopic evidence of invasion through the basement membrane into the surrounding stroma; but IDC, by definition, show signs of invasion of stromal tissue, often with vascular and/or lymphatic vessel involvement. In other words, conventional histological and radiological techniques (e.g. bilateral mammograms) cannot detect with adequate precision the ongoing carcinogenic events in many cases of women at risk.

Patients with head and neck squamous cell carcinoma (HNSCC) often develop multiple (pre)malignant lesions, ranging from leucoplakia to other cancers. This led Slaughter et al, way back in 1953, to postulate the concept of ''field cancerization.'' The incidence rate of second primary tumors following a first diagnosis of HNSCC is 10 to 35%, depending both on the location of the first primary tumor and the age of the patient. The carcinogens associated with HNSCC (alcohol and tobacco smoking) are thought to induce mucosal changes in the entire upper aerodigestive

tract (UADT), causing multiple genetic abnormalities in the whole tissue region. Similar arguments apply also to other tobacco-related cancers, like transitional cell carcinomas of the urogenital tract or bronchogenic carcinomas. An alternative theory for these observations is based on the premise that any transforming event is rare and that the multiple lesions arise because of the widespread migration of transformed cells through the whole UADT. However, most field changes appear to be induced by smoking, supporting the theory of carcinogen-induced field cancerization rather than field cancerization due to migrated transformed cells.

Other possible causes of ''field carcinogenic events'' can involve hormonal factors (e.g. changes in the ovaries, breasts or prostate), inflammation and hyperemia (increased proliferative and angiogenic activity in chronic cystitis, gastritis, esophagitis or colitis), chronic viral infections (e.g. Hepatitis B virus for hepatocarcinomas, Epstein-Barr virus for nasopharyngeal carcinomas or some lymphomas), aberrant methylation linked to aging, free-radical induced DNA damage (e.g. for cancers of the gastrointestinal tract), skin exposed to ultraviolet irradiation (e.g. actinic keratosis and squamous cell carcinomas), ionizing radiation-induced damage, or aberrant morphogenetic pathways. It is also possible that different carcinogenic pathways operate in different tissue fields belonging to the same organ. For example, adenocarcinomas of the right side of the colon are often associated with clinical and molecular characteristics different from those of adenocarcinomas of the colorectal region.

Even in breast cancer, the reported incidence of multicentric or multifocal lesions in areas away from the primary tumor in mastectomy specimens ranges from 9 to 75%, depending on the definition of multicentricity, the extent of tissue sampling and differences in the histological techniques of examination. Therefore, multifocality or multicentricity of breast cancers may in fact be a lot more common than is currently acknowledged.

In this context, the old ''Field Cancerization'' theory by Slaughter, and the more recent ''Multi-step Carcinogenesis'' model by Fearon and Vogelstein can now come together in a single model: Sequential Field Cancerization.

If it does require some seven sequential carcinogenic ''genetic hits'' in a single cellular clone for a malignant tumor to develop, it is mathematically more likely to occur in a tissue with a high background of genetic alterations in neighboring cellular clones, than in a tissue with a low background of such alterations, or with no detectable carcinogenic mutations at all (Figs. 1 and 2).

The probability of a single clone accumulating 7 independent but sequential genetic alterations leading to a malignant phenotype, without any similar events occurring in neighboring cells, would seem to be rather low. This simple conclusion, and our ability to measure ''background carcinogenesis'' in different parts of the body, might lead to several unexpected implications. Technology is just beginning to be sufficiently sensitive to start testing the hypothesis. One potential technical problem is that in premalignant tissue, the ''signal'' (e.g. relevant oncogenetic lesions) might be muted by the ''noise'' (normal genome of most of the cells in the tissue), until the premalignant clones have expanded enough to become more numerous locally than normal cells. However, it is only a matter of time before this goal is technically achievable.

A possible future objective is the development of a combined histological

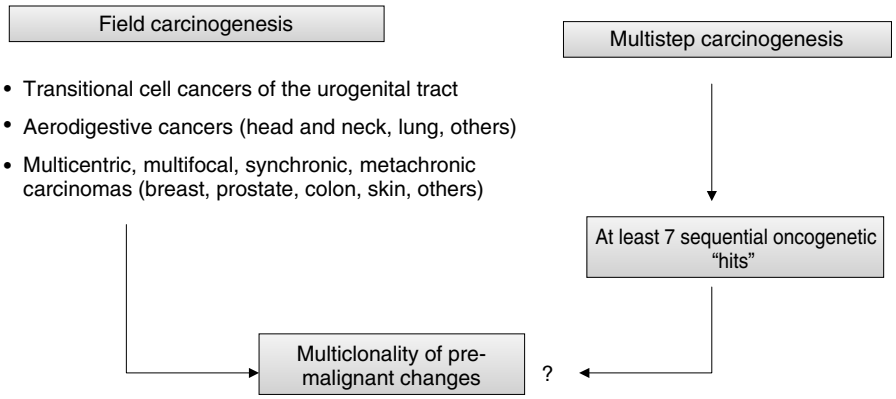

Fig. 1 Multiclonality of premalignant changes.

	Normal mucosa	Profilerative	Dysplastic
No mutations	I a	I b	I c
< 3 mutations	II a	II b	II c
> 3 mutations	III a	III b	III c

Fig. 2 Combined histological and molecular staging system of premalignant changes. Numbers inside the drawings refer to numbers of relevant gene mutations/deletions/amplifications identified in various regions of the breasts. Carcinogenic pathways may differ depending on the specific combination of genetic (and epigenetic) changes. (Reproduced from Bronchud, M. H. (2002) Is cancer really a ''local'' cellular clonal disease?, *Medical Hypothesis* **59**, 560–565. With Permission of Elsevier Science.)

and molecular staging system (Fig. 2). For example, after a follow-up of 5 to 10 years, one would expect more new cancers to develop in group IIIc of Fig. 2 (dysplastic changes and three or more significant mutations identified), than in group Ia (normal histology and no mutations identified).

There is a growing number of experimental findings in support of this complex concept. Among the first was the observation by Azadeh Stark and colleagues from various American institutions, that women with benign breast biopsies, demonstrating both HER-2/neu amplification and a proliferative histopathological diagnosis (either typical or atypical hyperplasia), may be at a substantially increased risk for subsequent breast cancer (up to more than sevenfold) compared to normal.

The clinical application of this concept and technology should help to classify patients into various relative risk groups early in the development of a malignant disease, allowing a tailor-made program for follow-up and screening, as well as more appropriate chemopreventive and therapeutic interventions. For example, a suitable combination of relevant biomarkers might help clinicians to identify smokers at high risk of developing lung cancers (approximately 10 to 15% of frequent smokers). Being confronted with a personal risk of cancer, rather than a general statistical risk, is a potent motivation to quit smoking and to undergo more frequent health checks (like high-resolution CT scans to detect isolated pulmonary nodules).

Some smokers may be protected because of genetic polymorphisms of enzymes involved in the molecular activation of pre-carcinogens present in tobacco, whereas others may be more vulnerable to the carcinogenic effects because of genetic defects in DNA-repair enzymes. Some molecular changes associated with aging and carcinogenesis might be epigenetic (e.g. promoter hypermethylation) rather than genetic. Even some pediatric malignancies might be secondary to abnormal morphogenetic events *in utero*.

It has been estimated that in the USA alone some 30% of people above the age of 60 can be found, by colonoscopy, to have adenomas of the colon, 70% or more of men above the age of 80 will have IEN of the prostate, 30% of people aged 60 or more have actinic keratosis on their skins, 20% of sexually active women above the age of 40 may have some degree of cervical IEN, at least 40% of heavy smokers can show metaplastic or dysplastic changes in their bronchial mucosa, and some 20% of women with dense mammograms and aged more than 50 may show atypical cells on ductal washings from the nipple or ultrasound-guided fine-needle aspirates.

The use of a battery of genetic or protein biomarkers relevant to each of the main cancer types may soon help us to better define individual cancer risks, and to measure background carcinogenesis in individual tissue samples. Perhaps, not too long from now, oncology units will be devoted to the treatment of carcinogenesis just as much as to the treatment of cancer.

One crucial difference between normal cells and transformed cells *in vivo*, which is difficult to prove experimentally but can be deduced, is that during cancer development, the effects of mutations are likely to be persistent, whereas most regulatory intercellular signals (particularly of ''paracrine'' nature) in normal cells are likely to be terminated by changes in cell position, production of signals, or modulatory effects on membrane receptor state. In normal tissues, the quantitative levels of signaling have been shown to be very important; signaling episodes, moreover, can have very different frequencies, and a specific cell can be influenced by a long-term signal while responding to a different signal of shorter duration. This does require that normal cells can sometimes remember a decision indefinitely, and can terminate their response to a specific signal, so that exposure to a new signal, or even the same signal, can subsequently produce a different molecular response.

The fact that cancer cells have lost, at least in part, this ''position-dependent'' obedience to signals, to the extent that they can even grow into distant metastases, makes them life threatening to their host organisms. Some sort of position dependence, however, is likely to remain even for most cancer cells, because their site of seeding and metastatic growth is not random, but depends on a number

of cell adhesions and microenvironmental predisposing factors.

2 Cancer as a Disease Process of Key Regulatory Pathways

The basic mechanisms controlling classical metabolic regulatory pathways have been known for many years. For example, the ''citric acid cycle'' (postulated by Krebs in 1937), the central role of ATP in energy-transfer cycles (postulated mainly by Lipmann in 1939–41), and Mitchell's intriguing hypothesis (1961) to explain the mechanism of oxidative and photosynthetic phosphorylation, to name but a few, have been part of biochemistry textbooks for decades. Some twenty years ago, the structure of DNA had already been known for over twenty years before that, and yet eminent scientists were pessimistic about real therapeutic progress in oncology.

In contrast, regulatory pathways involved in the complex regulation of cell growth, differentiation, senescence, and cell death are only recently being gradually understood. Although we are still largely unable to draw schematically precise cell-type-specific regulatory pathways, research efforts are intensifying, and our knowledge is rapidly expanding.

Growth and differentiation must be tightly controlled in any organism. Curious though it may seem, recent research suggests that fractal networks for transporting the materials essential for life, for example, nutrients, water, and oxygen, may be prime movers in determining shape and form (morphology) in Nature. A series of key papers by Geoffrey B. West, a theoretical physicist at Los Alamos National Laboratory, James H. Brown, a biology professor at the University of New Mexico, and Brian J. Enquist, a postdoctoral biologist at the nonprofit Santa Fe Institute, have reduced to just three general principles the allometric scaling laws, that are major determinants of most anatomical and physiological variables of organisms as they increase in body size.

In the year 2001, which was the hundredth anniversary of the institution of the Nobel Prizes, three of the leading investigators in the field of Cell Cycle Control were awarded the Nobel Prize for Physiology and Medicine. The American scientist Leland H. Hartwell of the Fred Hutchinson Cancer Research Center, and the British scientists R. Timothy Hunt and Sir Paul M. Nurse, both at the Imperial Cancer Research Fund in London, received this prestigious award for 'the confluence of two different approaches to learning about the molecular machinery regulating the cell cycle'.

While Hartwell was screening for temperature-sensitive mutants in the yeast *Saccharomyces cerevisiae* in the 1960s and 1970s, he identified a large series of genes that, in mutant form, arrested mitosis. This led him, and former postdoctoral researcher Ted Weinert, to hypothesize that 'checkpoints' regulate the sequence of events in mitosis (3). Even as Hartwell was uncovering these genes, Paul Nurse was identifying, in a different yeast (*Schizosaccharomyces pombe*), a protein kinase (CDC2) that is a key component of the maturation factors that drive cell division. Nurse then took a human cDNA library and eventually cloned a human CDC2, having observed the striking structural homology of these key regulatory molecules, that indicated a high degree of evolutionary conservation in different species.

Working at the Marine Biological Laboratory in Woods Hole, Mass., in the early-1980s, Hunt solved a crucial piece of

the cell cycle puzzle. In sea urchin oocytes, and later in frogs, Hunt identified proteins whose levels rose and fell throughout the cell cycle. He called them *cyclins*, and they were later found to be necessary in activating the ever-present kinases, like CDC2. Together a cyclin and a cyclin-dependent kinase (CDK) push the cells along the cell cycle regulatory checkpoints.

Previous work by others had already opened the path to these important findings. For instance, back in the early-1970s two scientists, Yoshio Masui and L. Dennis Smith, transferred the cytoplasm from activated frog oocytes to naïve oocytes arrested in meiosis, and identified a substance they called *MPF* (*maturation promotion factor*). Almost twenty years later, that substance proved to be none other than the CDK/Cyclin heterodimer.

In the year 2002 the Nobel Prize was awarded for seminal discoveries in another key area of biological relevance: the genetic regulation of organ development and programed cell death, or apoptosis. The winners of the Prize were the British scientists Sydney Brenner and John Sulston, and the American scientist Robert Horvitz. They discovered that specific genes control the cellular death program in the nematode worm *Caenorhabditis elegans*. This worm, approximately 1-mm long, has a short generation time and is transparent, which makes it possible to follow cell division directly under the microscope. The fertilized egg cell undergoes a series of cell divisions leading to cell differentiation and cell specialization, eventually producing the adult worm. In this organism, all cell divisions and differentiations are invariant that is, identical from individual to individual. This made it possible to gradually construct a precise cell lineage for all cell divisions. During the development of the organism, 1090 cells are generated, but precisely 131 of these cells are eliminated by programed cell death. This results in an adult nematode (the hermaphrodite), composed of 959 somatic cells. Again, most of the multiple genes controlling programed cell death have human equivalents (Apoptosis Pathways).

Thanks to the Human Genome Project, we now know that there are between 30 000 and 35 000 genes in the Human Genome, and 18 000 in the nematode worm. Both the Cell Cycle Control genes and the Programed Cell Death genes are crucial for carcinogenesis, and obvious targets for cancer therapy. In fact, optimal curative cancer therapies should include combinations of drugs that not only cause cell cycle arrest in tumor cells, but also lead to their apoptosis.

Recognizing that much of the cell's work is done not by individual proteins but by large macromolecular complexes, researchers are increasingly trying to map protein–protein interactions throughout the cell. The new term *Interactome* has been proposed to define this new type of ''cartography'' describing the main functional interactions of single proteins and protein macrocomplexes. For example, the map of the *C. elegans* interaction network, or interactome, links 2898 proteins (nodes) *via* 5460 interactions (edges).

It seems likely that, with time, different family patterns of ''malignant interactomes'' will be gradually identified, each with its unique ''key pathogenetic changes'' caused by the specific abnormal regulatory pathways implicated in its carcinogenesis process.

Over the past few years, researchers engaged in the nascent field of ''interactomics'' have been busy deconstructing these molecular machines, mapping protein–protein interactions in bacteria, yeast, fruit flies, nematodes, mice, and humans.

The resulting charts have exposed the functions of previously mysterious proteins, have helped drug companies *hone* their development efforts, and are laying the foundations for systems biology. Some proteins appear to be rather ''promiscuous'' in their interactions. Drugs targeting these so-called *sticky proteins* have the potential to produce troubling side effects. Pharmaceutical companies, therefore, would be better served by focusing on those molecules that appear more selective, and by limiting themselves only to the particular process they are targeting.

It must be said, however, that doubts about the validity of interactome information remain. Although ''data rich,'' these studies produce lower-quality results than would a scientist who devotes years to a single protein. High throughput means that you do things fast, but the information can be ''data-rich and analysis-poor.'' Again, as is true for most of Molecular Oncology today, ''the trees may not allow us to see the woods.''

Y2H data especially are open to question, because the technique essentially amounts to a genetic trick. It relies on artificial fusion constructs: often, mere fragments of the full-length protein are introduced into cells, forced into the nucleus, and overexpressed. False-positive results are inevitable.

The vast majority, 93%, of yeast proteins makes five or fewer connections, yet only one in five such proteins is essential.

Deletion of highly connected proteins (those joining 15 or more proteins) is three times more likely to be lethal.

Recently, Marc Vidal's team at the Dana-Farber Cancer Institute in Boston expanded this study by examining coexpression of genes linked by hubs. Their conclusion: all hubs are not created equal. Some, called *party hubs,* contain proteins that interact simultaneously, whereas *date hubs* contain proteins that interact at different times and locations.

The Dana–Farber group infers a modular architecture for the proteome, in which date and party hubs operate at different organizational levels. Party hubs function to assemble individual molecular complexes, or modules. These modules, in turn, are linked at a higher level, using date hubs. Thus, the date hub calmodulin links modules for cation homeostasis; budding, cell polarity, and filament formation; protein folding and stabilization; and the endoplasmic reticulum.

There can be little doubt that if this new branch of biological research (Interactomes), develops to the point of not only mapping the functional protein–protein interactions in any given key regulatory pathways like the TGF-beta pathway but also predicting, on the basis of genomic and/ or proteomic data for any given cancer tissue, the dynamic functional consequences of the intrinsic molecular changes observed in tumor specimens, and the manner of their response to external manipulation by drugs or ionizing radiation, then we can end up with truly useful tools for both drug development and clinical follow-up.

With so much disparate data available, the challenge for researchers is to integrate that information into a single ''interaction network,'' and then to take decisions relating to research and development of new anticancer drugs. These could, for example, be based on new visualization tools such as ''Cytoscape,'' jointly developed by the Institute for Systems Biology at the University of California at San Diego, and the Memorial Sloan-Kettering Cancer Center in New York. Cytoscape, a technology still undergoing development, incorporates interaction data with

other large-scale genomic information to build networks of cellular processes and pathways. Through the Systems Biology Markup Language (SBML), it can also communicate with other SBML-enabled programs to test mathematical simulations of cellular events.

Unraveling the twisted skeins of the relative contributions of altered regulatory pathways to the cancer phenotype of each individual cancer can be certainly annoying. Simplicity is elegant, but it can also be deceiving. In spite of the unquestionable success of many reductionistic approaches in science, we should never underestimate complexity, as often going against nonsense sensible arguments is just so much blowing against the wind.

However, at this stage of knowledge, it does seem likely, and it remains highly desirable, that most of these key regulatory cascades will converge into a number of key regulatory events: the DNA replication at multiple different sites in the genome, the coordinated expression or suppression of a battery of genes, the culmination of the developmental history and cell fate of any given clone, the progressive modification of the biological ''clock-like mechanisms'' that drive differentiation and aging, and the three-dimensional structure–function relationships of chromatin.

A very simplistic, and classic Cartesian, way to look at what happens in cancer cells is to describe the main functional implications of genetic events (point mutations, deletions, translocations, etc.) in binary terms (GF: gain-of-function; LF: loss-of-function *versus* N: normal function) in a table such as the one that I have called *'Matrix of Targets'*.

Each cancer may have, because of its own genetic and epigenetic backup and clonal history, a different Matrix of Targets. This adds to the complexity of potential curative therapies, but can eventually translate into therapeutic combinatorial models of several drugs or biological agents capable of stopping the growth and proliferation of cancer cells, reducing their invasive or metastatic properties, or even restoring their differentiation or apoptotic pathways.

Another way to look at things is to take the view that certain key genetic changes are the true and main pathogenetic mechanisms for any single cancer, because these key genetic changes (e.g. the abl-bcr fusion gene, associated with the Philadelphia chromosome in Chronic Myeloid Leukemia) lead to a much wider pattern of changes in gene expression, up or down, thereby consolidating the malignant phenotype: increased and unrestrained cellular proliferation, loss of contact inhibition, lack of normal differentiation or presence of abnormal differentiation, genomic instability, ectopic expression of genes, angiogenic activity, acquisition of the invasive phenotype, the ability of cells to spread and seed at distant sites, and so on.

These key ''pathogenic genetic events'' would drive the clonal evolution of cancer cells in a way similar to the ''evolution genes'' postulated by Werner Arber, elegantly described in the chapter on ''Genetic Variation and Molecular Evolution'' in this encyclopedia.''

There is therefore a need, in Molecular Oncology, to follow very closely the rapidly accumulating knowledge on the molecular mechanisms that regulate gene expression.

Identifying genome-wide regulatory motifs is problematic because of their typically low consensus sequences. Grasping which transcription factors bind to such motifs is even more difficult, as numerous factors can bind to any one motif.

In two recent publications, Pugh and colleagues found that only 20% of yeast genes contained their TATA boxes, but they were all highly regulated in response to stresses such as heat and osmotic shock. Such genes generally use a multicomponent protein complex called *SAGA*, which is one of several complexes thought to bring the TBP to promoters. In contrast, genes without a recognizable TATA box appeared to use mainly another complex, TFIID, and were less involved in responding to stress. This could be an example of bipolar type of regulation.

Predicting gene expression from DNA sequence, and understanding the relative role of individual transcription factors in the development of normal tissues and in the oncodevelopment of cancers, are the clear goals of these technologies. However, these goals are still not within immediate reach.

Although probably no two cancers are 100% identical, in the same way as no two cancer patients are ever identical, the rational understanding of how altered regulatory pathways can lead to the development and consolidation of cancer cell clones, may provide us with some basic patterns of regulatory circuits associated with malignancy. To some extent these ''biochemical maps'' or ''carcinogenic patterns'' may be tissue dependent.

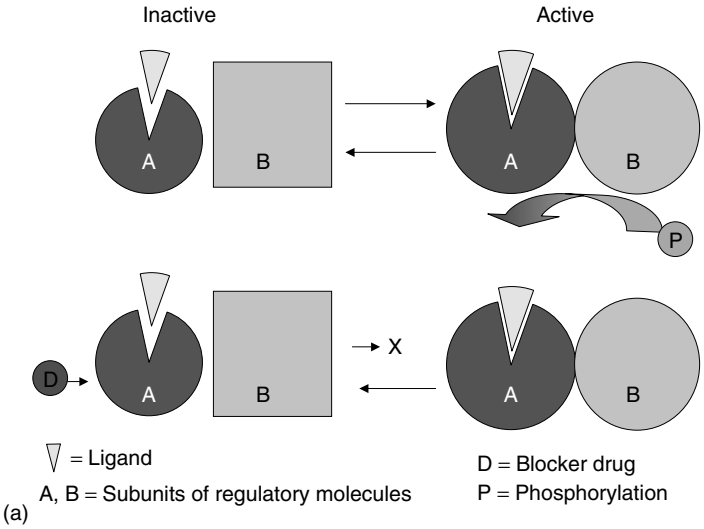
Most of these key regulatory processes, if not all, will have:

1. Upstream regulatory elements; for example, membrane-bound or membrane-associated.
2. Intermediate elements; cytosolic or bound to organelles, like mitochondria.
3. Downstream elements, transcription factors, DNA- or RNA-specific sequences.
4. Bottlenecks, Cross talk points and ''Achilles heels'' (Oncogene Addiction Hypothesis) of cancers.

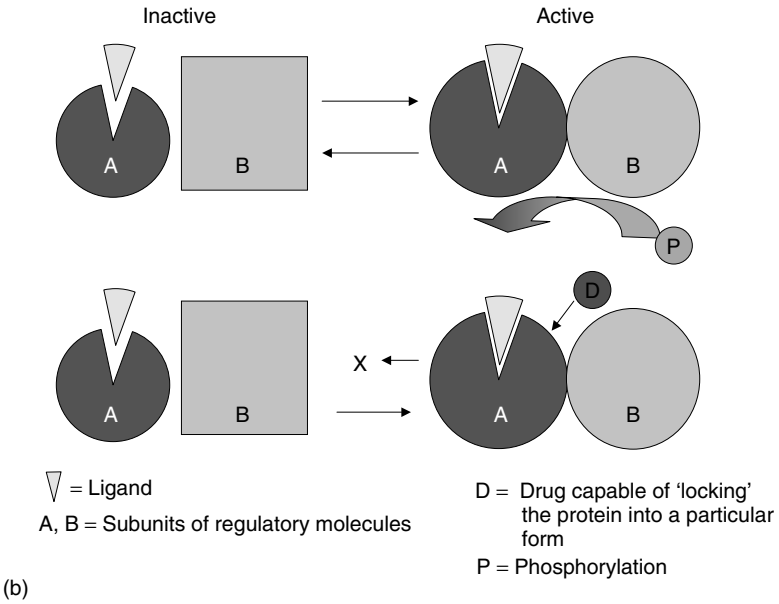
New cancer therapies will not be directed merely towards hitting the DNA synthesizing machinery but also towards selective targets at or downstream from abnormally activated catalytic functions (thereby abrogating the abnormal stimulatory signals), or at or upstream from inactivated or missing catalytic functions (switching on parallel or alternative regulatory pathways).

In simplistic terms, the new therapeutic drugs should, for example, lock or inhibit activated proto-oncogenes in their inactive state, or somehow lock tumor suppressor proteins in their active state, which is the one normally responsible for inhibiting entry into S-phase or mitosis, or maintaining the normal differentiation and apoptotic pathways (Fig. 3). In other words, as regulatory proteins are usually present in normal cells in either an active form or an inactive form, and the chemical equilibrium between the two forms depends on the regulatory microenvironment of the cell, new targeted therapies should be able to correct, or at least limit, the malignant phenotype by restoring the normal balance between stimulatory and inhibitory signals within the cell.

This concept of regulatory pathways involved in cell behavior is the basis of a new biochemistry. Crucial alterations in this new biochemistry, perhaps as few as five distinct key molecular changes, may be enough to transform a normal human cell into a tumor cell. It appears that because of their higher complexity, human cells are more difficult to transform than rodent cells. Perhaps surprisingly, more simple organisms, such as *Drosophila*



(a)



(b)

Fig. 3 Hypothetical new target-oriented therapies. (a) Oncogenes as targets. The new anticancer agents should lock the oncogenic protein in its *inactive form*, either by binding to the active site, or by binding to an allosteric regulatory site; (b) Tumor suppressors as targets. The new anticancer agents should do the opposite of what is described above. They should lock the tumor suppressor protein into its *active form*, that is, the one capable of inhibiting the cancer phenotype, by either binding to the relevant active site or to allosteric regulatory sites. (From M. H. Bronchud. (2004) *Principles of Molecular Oncology*, reprinted by permission of Humana Press.)

melanogaster flies, very rarely develop malignant cells, in spite of their ability to develop mutations in experimental systems. There has been no clear explanation for this apparent paradox.

Phosphate atoms are again involved in this ''new biochemistry,'' because protein phosphorylation is the common end-result of many signal pathways. It was back in 1937 (the same year Krebs postulated the citric acid cycle) that C. Cori and G. Cori began their outstanding studies on glycogen phosphorylation (the main store of sugars in the liver of mammals). However, it was not until 1988 that Tonks obtained the first partial sequence of a tyrosine phosphatase. Today, it has been suggested that the human genome might contain as many as 2000 kinase genes and up to 1000 phosphatase genes.

A ''normal'' cell, under ''normal'' circumstances, probably decides nothing by itself (there is no cellular ''free-will''), but merely obeys orders. Normal cells can signal each other in many different ways: through pores in the membranes (gap junctions or plasmodesmata), or because of specific membrane receptors that recognize soluble or bound ligands (endocrine, paracrine or autocrine mechanisms), or in some special cases (e.g. neurones) by synaptic transmission. However, a cancer cell (because of mutations, amplifications, translocations or deletions) makes mistakes (misinterpreting the normal orders or even making them up for the wrong reasons). And it cannot help doing so because its software has gone badly and progressively wrong. Cancer cells do not have exactly the same underlying chemistry as the normal cells of the body.

This makes them ''strong,'' but also, paradoxically, makes them vulnerable to more specific and selective combinations of drugs.

Most of these, second, third, fourth, and so on, intracellular messengers are binary: they are either switched on or off (by phosphorylation-dephosphorylation, for example). At any one time a number of + and − signals travel from the cell membrane to the nucleus (and, perhaps, also backwards). These signals are irreversibly altered in cancer cells. The normal balance between the ''on'' and ''off'' signals is altered in cancer cells.

To reestablish the normal circuits, or to kill the cell by misleading it into apoptosis, we must learn to be clever, understand these key pathways, and develop drugs to block them or to activate alternative complementary pathways. Thus, cancer is a disease of regulatory pathways. There may not be ''magic bullets'' to kill all cancer cells. The signal transduction pathways involved in the proliferative response to various growth factors and mitogens are extremely complex and interactive. They do not act as simple linear cascades. The so-called *'cross talk'* is an invariable feature. The new biochemistry is essentially the network of sensing and signaling in cell homeostasis.

Several key questions remain:

1. How much selectivity can we expect to achieve with new drugs that will manipulate these complex signaling pathways?
2. Will these new drugs be cytostatic, or cytotoxic, or both?
3. How will these new drugs be obtained: serendipity; rational drug design; high-throughput screening; combinatorial chemistry; antisense technologies; gene vectors; antigrowth factors; monoclonal antibodies?
4. Will they imply chronic therapies or acute therapies?
5. Will they have new, and at times unexpected, toxicities?

6. Will some malignant clones still develop resistance to signal transduction therapy?

Some of these questions can already be answered by the available examples of targeted therapies in cancer. For example, it seems that most of the new drug entities acting on cell surface growth factor receptors, or cytosolic downstream regulatory elements, for example inhibitors of the EGFR (Epidermal Growth Factor Receptor) or associated tyrosine-kinase activities, are mainly ''cytostatic'' *in vivo* rather than ''cytotoxic''; they are fairly nontoxic (though, at times, with new unpredicted toxicities, like acneiform skin rashes), and are best administered on a continuous long-term protocol.

A very competitive area at present is in fact represented by the pharmacology of epidermal growth factor receptor (EGFR) targeting. EGFR signaling pathways play a key role in the regulation of cell proliferation, survival, and differentiation. Monoclonal antibodies, mAbs, among which C225 (Cetuximab), and ''specific'' tyrosine- kinase inhibitors, TKIs, like ZD1839 (Iressa) have been developed, clearly differ in their mode of action at target level. The primary action mechanism of C225 (a chimeric mAb) is a competitive antagonism of EGFR. Independent of the phosphorylation status of the receptor, the EGFR-C225 complex is subsequently internalized. On the other hand, TKIs act on the cytosolic ATP binding domain of EGFR by inhibiting EGFR autophosphorylation. Depending on the nature of the TKI, EGFR inhibition can either be reversible, as with drugs like ZD1839 and OSI-774, or irreversible, as with PD 183 805.

There are still rather few published studies dedicated to examining in detail the various possible mechanisms of resistance to EGFR targeting, irrespective of the anti-EGFR drug considered. There is also some confusion as to the precise cytosolic and nuclear downstream effects following EGFR targeting, particularly when combined with conventional cytotoxic drugs. Moreover, although some consensual findings tend to suggest a link between the level of the EGFR protein target (as detected by IHC) and the intrinsic efficacy of the targeting drug, more pharmacodynamic studies *in vivo* are needed to establish convincing conclusions regarding EGFR levels and targeting efficacy on which clinical strategies can be based with confidence.

Some new, but not unexpected toxicities have already been described for many of these new targeted therapies. For example, the anti-VEGF monoclonal antibody Bevacizumab (Avastin), indicated in combination with intravenous (iv) 5-FU based chemotherapy as first line or second line treatment for patients with metastatic carcinoma of the colon or rectum, can result in the development of gastrointestinal perforation (2% of cases) and wound dehiscence, in some cases resulting in fatality. The appropriate interval between termination of Avastin and subsequent elective surgery required to avoid the risks of impaired wound healing/wound dehiscence has not yet been precisely determined. Moreover, this exciting new therapeutic molecule can also cause unexpected hemoptysis, and in early studies with squamous lung cancers, the incidence of serious or fatal hemoptysis reached up to 31%.

These considerations can lead to some methodological problems in the design of clinical trials. The primary endpoints in phase III randomized clinical studies should remain those reflecting survival of patients, but secondary end points should include measurable quality

of life, disease-related symptoms, performance status, and time to disease progression.

On the other hand, primary endpoints in phase I and II studies should include, besides toxicity and classical pharmacokinetics, data on relative efficacy and sophisticated *in vivo* pharmacodynamics, ranging from changes in genomics (gene expression profiling) and proteomics (protein expression, intracellular localization, and posttranslational modifications) of key targets and downstream effector molecules in tumors in response to the new drug. Additional surrogate endpoints to be considered in phase II studies include relevant *in vivo* dynamic changes on positive emission scanning (PET), new dynamic molecular imaging like dynamic enhanced magnetic resonance imaging (DCE-MRI), and other methods to quantify changes in the growth kinetics of tumors, and for the subset identification of cancers that respond (*versus* those that do not respond) to the new therapies.

3 Main Types of Molecular Markers of Cancer Cells: Genetic and Epigenetic Changes

There are different types of tumor markers:

1. *Genetic markers*: In both hereditary and nonhereditary tumors. These genetic changes can be detected by conventional DNA sequencing techniques, Real-Time Kinetic PCR-based techniques (RT-PCR), gene expression microarrays and DNA microarray-based sequence analysis, comparative genomic hybridization (CGH), fluorescence *in situ* hybridization (FISH), and a variety of new rapidly evolving molecular methods.
2. *Pharmacogenetic markers*: Pharmacogenetic markers are hereditary genetic polymorphisms that may influence the *in vivo* anticancer drug metabolism (activation of pro-drugs, or de-activation), or, perhaps from a more relevant clinical point of view, the likelihood of drug-related serious toxicities because of inherited metabolic polymorphisms. Thus, as an example, genetic variants in the UDP-glucuronosyltransferase 1A1 gene products can predict the risk of subsequent treatment-related severe neutropenia by irinotecan, a fairly active cytotoxic drug in colorectal cancers.
3. *Cellular and tissue markers*: Detected by conventional histopathology or immunohistochemistry, IHC, or by more sophisticated proteomics or genomics technologies; for example, Kodadek has described ''protein-function arrays'' and ''protein-detecting-arrays'', and Kononen et al. have described ''tissue microarrays'' that can allow the molecular study of several hundred tumor specimens in a single paraffin block.
4. *Circulating cancer markers*: The ones traditionally used in the clinic include a variety of glycoproteins, oncofetal antigens, hormones or pro-hormones, tissue-related secreted products, and so on. Some of these are (with the main cancer types associated to increased serum levels): CEA (colon cancer, lung cancer, breast cancer, etc.), CA125 (ovarian cancer), PSA (prostate cancers), Beta-2-Microglobulin (lymphoproliferative diseases), LDH (a nonspecific marker of tumor bulk and aggressive disease in Non-Hodgkin's Lymphomas and other cancers), CA19.9 (pancreatic cancers and other cancers), CA 15.3 (breast cancer and others), HCG-*beta* (nonseminomatous

germ cell cancers), AFP (hepatocarcinomas and nonseminomatous germ cell cancers), Immunoglobulin levels (multiple myelomas), and Thyroglobulin (Thyroid carcinomas). More recent markers detectable in serum or other body fluids (including urine, feces, sputum or bronchial washings) include DNA fragments of oncogenes, soluble growth factor receptors (like HER-2), cytokines (IL-6 for metastatic renal cell carcinoma), and other substances.

Some of these markers are already used routinely in clinical practice (e.g. several circulating cancer markers are useful for the diagnosis, prognosis, and follow-up of some cancer types), while others are being investigated as a source of important prognostic information or even as predictors of response to chemotherapy or radiotherapy (e.g. several cellular and tissue markers). Still others are being explored, in the context of genetic counseling, as potentially useful to screen for hereditary cancer predisposition, for example, BRCA-1 and BRCA-2 for breast and ovarian cancers; RERs and several MMR genes (hMSH2, hMLH1, hMSH6, hPMS1, hPMS2, etc.) for families with hereditary predisposition to colon cancer (HNPCC); and the APC gene in families with FAP (familial adenomatous polyposis).

One of the most peculiar types of molecular markers in human cancer cells is the increased expression of normal or abnormal ''Telomerases,'' and significant progress is being made in understanding how it works. In contrast, despite being implicated in many important regulatory pathways including DNA repair, protein ubiquination and cell cycle control, the exact mechanisms by which inactivation of the tumor suppressor gene BRCA1 or 2 might lead to malignant transformation, particularly in families with high risk of breast and ovarian cancers, remains speculative.

5. *Epigenetic markers*: I shall describe very briefly some of the described ''epigenetic'' markers. Unless genetic therapies develop to the point where it will truly be possible to perform *in vivo* some form of curative ''genetic surgery,'' for example, either replacing a missing tumor suppressor gene with a normal wild-type counterpart, or removing an activated oncogene, in every single cancer ''stem cell'', or cancer ''progenitor cell,'' and without unbearable side effects or deleterious long-term consequences, it is perhaps wiser and more relevant to consider as primary targets for therapy the epigenetic and protein elements associated with carcinogenesis, rather than just the ''genetic'' elements.

We should not forget that, ever since Paul Ehrlich described them in 1913, the classic biochemical targets for drug action are:

1. Inhibition of the active site of an enzyme (or competition with the natural ligand of a hormone or growth factor receptor);
2. Allosteric inhibition and false feedback inhibitors of enzymes or growth factor receptors;
3. Other inhibitors acting outside the active center (exoinhibitors);
4. Double blockade (e.g. where pairs of compounds are used together to block a single biochemical pathway).

The recent progress in the physical mapping of the Human Genome is already pointing toward a ''Post-Genome Era.'' Automated or semiautomated devices capable of reading thousands of genes are already

available. Genomics and proteomics are here to stay, but their routine use in the clinic obviously requires proof of efficacy and judicious use. Apart from technical problems inherent in these techniques, which time will solve, there are some general obstacles to realizing their promise:

1. the lack of genetic markers to cover 100% of all tumors;
2. the lack of knowledge about the functional implications of most genetic defects (the precise maps of these regulatory pathways are still under investigation, and may be to some extent tissue specific);
3. the widespread location and heterogeneity of many of the gene mutations (particularly in large genes);
4. the lack of knowledge about the prevalence of these genetic defects in an apparently healthy population (people with no detectable cancer or histologically malignant lesions; for example, presence of molecular lesions in endometriosis or in apparently normal oral or bronchial mucosa);
5. the lack of knowledge about the significance (in terms of risk of developing cancer) of each of these genetic lesions individually or in different combinations. For example, which combinations of genetic lesions are more relevant to neoplastic transformation in a given tissue?

Epigenetic markers of cancer are probably secondary and later events in most of carcinogenesis, but their importance had also been suspected for several decades. The relevance of these epigenetic changes, and particularly of changes involving the three-dimensional conformational structure of chromatin, making it more or less accessible to polymerases and Transcription Factors, have enabled these markers to gain popularity, and they can have significant therapeutic potential.

Methylation of DNA serves as an epigenetic method of modulating gene expression, and it has been demonstrated that hypermethylation silences a number of tumor suppressor genes including most of the CKIs. Epigenetic mechanisms of carcinogenesis are increasingly coming into focus. Recent findings indicate that aberrant methylation can also be detected in the smoking-damaged bronchial epithelium of cancer-free heavy smokers, suggesting it as an ideal candidate biomarker for lung cancer risk assessment, and potentially useful for the monitoring of chemoprevention trials. Of 12 lung cancer cell lines lacking a deletion or critical mutation in *Rb* or *CDKN2A*, which codes for the CKI p16(INK4A) protein, all were found to be methylated at exon 1 of the *CDKN2A* gene.

Other studies have also shown that underexpression of this gene *CDKN2A* is frequently seen in early preinvasive lesions of squamous cell carcinoma of the lung and cervix.

Some recent work in Korea, at the Samsung Biomedical Research Institute, suggests that tumor-specific methylation of the *p16* gene, and other lung cancer-related genes, like Ras association domain family 1A (*RASSF1A*), H-cadherin, and retinoic acid receptor *beta* (*RAR-beta*) genes may be suitable biomarkers, detectable by methylation-specific polymerase chain reaction (MSP), for the early detection of nonsmall cell lung cancers in bronchial lavage fluids of smokers.

While at least three functional DNA methyltransferases have been identified, the most abundant is DNMT1, which is mainly responsible for methylation during DNA replication. DNMT1 localizes at replication foci, at least in part by interacting with the proliferating cell

nuclear antigen known as PCNA, which is a subunit of DNA polimerase *delta* (that can also bind to the CKI p21 protein). The enzyme DNMT1 catalyzes the covalent addition of a methyl group from a donor S-adenosyl-methionine to the 5 position of cytosine, predominantly within the CpG dinucleotides in highly repeated transposable elements.

These elements are termed *parasitic* because of their resemblance to viral DNA and their ability to move between different chromosomal sites. During embryogenesis there is an initial generalized demethylation of DNA, followed by a specific adult pattern of methylation. While roughly half of the 5′ promoter proximal elements contain CpG islands, they are not usually methylated in normal tissues. But cancers display a particular pattern of methylation. Overall they are hypomethylated, but they do have specific regions of hypermethylation, often associated with regions rich in tumor suppressor genes.

Several molecular variations of deoxycytidine have been developed to inhibit DNMT1, each modified at position 5 of the pyrimidine ring, and these have been reviewed recently. Four agents have been employed clinically: 5-azacytidine (azacitidine), 5-aza-2′-deoxycytidine (decitabine), 1-*beta*-D-arabinofuranosyl-5-azacytosine (fazarabine) and dihydro-5-azacytidine (DHAC). These agents are not new. Some are almost 40 years old, but other analogs such as ara-C and gemcitabine (already in clinical use as anticancer agents) do not inhibit methylation of DNA.

Because methylation of CpG islands in promoter-proximal regions is uncommon in normal cells, normal gene expression should be largely unaffected by these agents. But, at least in some leukemic cells, decitabine has also been found to increase the expression of the multiple drug resistance MDR1 gene product, and this could be clinically counterproductive.

Some studies with these inhibitors go back to the 1980s, for example the EORTC studies with decitabine, and others have been completed more recently. In general, response rates to these agents in solid tumors have been rather low, but more promising results have been obtained in hematological malignancies. Toxicities have been similar to conventional cytotoxics: granulocytopenia, thrombocytopenia, alopecia, nausea, vomiting, and diarrhea. The reason why these drugs have not yet translated into better clinical outcomes, in spite of a sound biological basis for their activity in human malignancies, is not clear.

Acetylation and deacetylation of histones can also provide new insights into how to modify the gene expression patterns of normal and cancer cells.

Methylation of DNA has been shown to induce recruitment of histone deacetylase, which inhibits transcription, and agents have been devised that inhibit this deacetylase. The combination of a DNMT inhibitor and a histone deacetylase inhibitor might be a logical way to activate tumor suppressor gene expression (e.g. CKIs), and a number of preclinical studies are in progress.

Chromatin is no longer considered to be a passive scaffolding for nuclear DNA. At the heart of chromatin's structure is the nucleosome, a complex of DNA wound around an octamer containing two molecules each of histone proteins H2A, H2B, H3, and H4. Histones contain two distinct domains. These are: the protein's amino-terminal tails, which protrude from the nucleosome core, rich in charged amino acids such as lysine and arginine residues; and the globular histone core domain that is mainly responsible for the

histone : histone interactions involved in nucleosome formation.

A number of posttranslational modifications occur in the histone tail domain, including acetylation, phosphorylation, ribosylation, methylation, ubiquitinylation, and glycosylation. Of these, the most widely studied is the acetylation of histone tail domains on specific lysine residues.

The steady-state levels of histone acetylation in the cell are maintained by a delicate balance between the action of histone acetyltransferases (HATs), and histone deacetylases (HDACs).

A number of methodological breakthroughs have allowed a better understanding of this process. Tightly compacted nucleosomes forbid general transcription factors, such as TFIID and RNA polymerase II holoenzyme, from interacting with promoter sequences of specific genes. It is becoming clear that many transcriptional activators actually direct two different types of chromatin remodeling enzymes to specific promoters: an ATP-dependent remodeling enzyme and a histone acetyltransferase.

The field of chromatin research was revamped in 1996 when C.David Allis and colleagues published evidence that the yeast Gcn5p protein, already known to positively regulate gene transcription, was actually a HAT. This acetylation may induce a conformational change that weakens nucleosomal DNA : histone interactions, making the DNA more accessible to transcription factors. Many other transcriptional coactivators have also been recently found to contain HAT activity. Other studies have identified several HDACs (including the mammalian HDAC 1 to 8), as well as large multiprotein complexes, including the so-called *RbAp-46* and *48 (retinoblastoma and histone binding proteins)*, that can undo histone acetylation and modify gene expression.

Recently, Strahl and Allis have proposed the existence of a ''histone code,'' whereby nonhistone proteins read the patterned display of various modifications on one or more histone tails, resulting in the regulation of downstream transcriptional events.

Considering all this new knowledge, it should come as no surprise that HATs and HDACs have also become potential targets for cancer therapy. They appear to act as both oncogenes and tumor suppressors, depending upon the genetic and epigenetic contexts. One interesting example is the variety of chromosome translocations, (often an undesired consequence of previous cytotoxic chemotherapy), that can affect the mixed lineage leukemia (MLL) locus. Thus, a MLL-CBP fusion protein maintains the HAC activity of CBP, and it can be highly oncogenic as a result of the specific targeting of the fusion protein to certain genes.

The field of HATs and HDACs modulating drugs is promising, but highly complex. To achieve selectivity, HATs must be highly targeted to specific genes, and this targeting depends on several structural protein motifs such as ''bromo domains'' and ''PHD'' fingers.

Allosteric inhibitors might be more selective and clinically useful than active site inhibitors. But traditionally, chemists have learnt how to develop suitable pharmacological compounds to interfere with active sites and substrate binding, rather than to interfere with the allosteric properties of a regulatory protein, or protein complex. Even modern automated or semi-automated ''high-throughput'' screens are usually designed for compounds affecting enzyme activity, rather than for those altering protein–protein interactions.

This is a major challenge for the whole field of new anticancer drugs development. Learning how to modify the allosteric properties of oncogenic proteins should become an important aspect of anticancer drug research.

4
The Era of 'Targeted Therapies'

4.1
Threats and Opportunities

Although the term ''target-oriented therapies'' has only recently been popularized in oncological literature, it must be acknowledged that hormone receptors (e.g. estrogen receptors in breast cancer, and testosterone receptors in prostate cancer) have been used as therapeutic targets by clinical oncologists for a rather long time.

In fact, even the antimetabolite 5-fluorouracil (5-FU), that is a common constituent of many conventional chemotherapy protocols (in 2002, for example, over 2 million patients with cancer were treated worldwide with this drug), was chemically synthesized back in 1957 by Heidleberger, but can also be regarded as a biochemically targeted molecule. This is because 5-FU's activity is based on the observation that uracil is preferentially used by cancer cells, and that fluorinated analogs of this base might ''selectively'' inhibit the functioning of DNA and RNA in cancer cells, by forming stable ternary complexes with the enzyme thymidylate synthase (TS), resulting in thymidine starvation and inhibition of DNA synthesis.

4.1.1 Threats

From the therapeutic research point of view, the real impact of Molecular Oncology is that it has provided us with many more potential targets for drug discovery than we can handle with our present ability to understand the real priorities, and our capacity to develop valid anticancer drugs in a relatively short period of time. As we move toward this new exciting era of cancer therapies (''Targeted Therapies'') we face several key problems:

1. Current cytotoxics have a very limited curative potential, except in rare cancers.
2. Most current cytotoxics are relatively ''old drugs'' and their patents are running out. New anticancer drugs are needed in the short term.
3. There seem to be more ''potential molecular targets'' for therapy than true industrial capacity to develop new effective drugs in the short term. In general, once the relevant oncoprotein is identified and purified, gene cloning allows the production of sufficient quantities to allow the determination of its main molecular mechanisms (catalytic or regulatory) and its three-dimensional structure. Appropriate molecules (e.g. those developed by empirical methods like high-throughput screening or by rational drug design) can then be tested *in vitro* and in preclinical models to determine their activity and toxicity, pharmacokinetics and pharmacodynamics.
More and more oncological units will be devoted to clinical testing of new drugs, and cancer research is likely to undergo a rapid growth, provided enough resources are made available. It could, perhaps, prove globally more rewarding to concentrate on normal regulatory proteins (e.g. upstream on the cell membrane, cytosolic or associated to organelles, like mitochondria or proteasomes, or at downstream ''bottlenecks'', or points of ''cross talk'') than

on mutated oncoproteins. The problem in this case, however, is that inhibition of normal downstream regulatory oncoproteins might prove more toxic than selective inhibition of mutated oncoproteins, or inhibition of upstream membrane-bound regulatory elements. Clinical oncologists, on the other hand, are well trained to cope with important toxicities, and highly effective methods to reduce nausea and vomiting, or drug-induced myelosuppression and serious infections have been developed over the past 15 years.

4. The average cost of bringing a new anticancer drug to market is still around 500 to 800 million US dollars, and the time from discovery to the market remains around 10 to 15 years. Both need to be considerably reduced.
5. New ''target oriented'' therapies will probably be more effective, and less toxic, but also more narrow in their indications, thereby limiting their potential markets.
6. New targeted therapies will require more sophisticated diagnostic tools than conventional cytotoxic chemotherapies, in order to correctly identify the right subset of patients most likely to benefit from such therapies. Conventional histopathology or immunohistochemistry (IHC) will not be enough to achieve this. This will add to overall costs.

   High levels of c-erbB-2 expression or c-erbB2 amplification must be used (by IHCS or FISH) to identify patients for whom Herceptin may be of benefit, but even in this group of patients only some 50% will show objective responses to the combination of Herceptin plus chemotherapy (30% if chemotherapy alone is used). The reasons for this are unclear. Theoretically, Herceptin, by interfering with signal transduction emanating from HER-2 (again, locking the oncogenic molecule into an inactive or less active form) should reduce the potential proliferative competitive advantage of cancer cells in comparison with normal cells.

   However, the additive or synergistic effects of cytotoxic drugs could be caused by as-yet-unknown effects of these drugs downstream on the signaling pathway. As a matter of fact, other inhibitors of EGFR (for example, inhibitors of the EGFR associated tyrosine-kinase activity), such as gefitinib, have not so far shown any significant survival benefit when used in the treatment of nonsmall cell lung cancer patients, in combination with platinum-based cytotoxics.

   Moreover, the relationship between tumor marker levels and sensitivity to new therapies may not be linear, or may depend on yet unknown circumstantial factors.

   For example, HER-2 inhibitors (in the case of Trastuzumab) can induce objective response rates in breast cancer patients, but often without clear evidence of a dose–response relationship in their response or survival, or in adverse events. The main predictor of response may be the degree of expression of the target molecule, as well as the intrinsic relevance of this target molecule to the cancer phenotype. Thus, response rates for single agent Trastuzumab in 111 assessable patients with metastatic breast cancer was 35% for patients whose tumors showed a 3+ staining of HER-2 by IHC, as compared to 0% for the case of tumors with only a 2+ staining. This suggests an interesting nonlinear relationship between marker expression and clinical response. The message, as

linguists have known for a long time, is that: 'the same word in a different context can give the final sentence a very different meaning'.

Thus, drug companies are well advised to present their phase II and III clinical studies with adequate and comprehensive biochemical (genomic or proteomic, or both) pharmacodynamic data to fully persuade health authorities and clinicians about the benefits of the new therapeutic agents, and the indications for their use.

7. The applications of pharmacodynamics are becoming increasingly important. We should be able to measure, in any given tumor, the direct and indirect genomic and proteomic effects of whatever changes a new drug is producing, or is meant to produce. We should also be able to put this usually complex type of information into some kind of model, so that it can be extrapolated to other tumors with different molecular compositions. Not an easy task, but one of the most exciting challenges ahead. Sound understanding of clinical and biological knowledge, as well as intuitive parallel thinking, good communication skills and an open collaboration within multidisciplinary teams can be really helpful. Paul Workman (2004) has suggested an ''Audit Trail'' for each new ''target oriented'' anticancer drug in development:
   - *Is the target expressed and is the pathway active?* It is important to understand the relationship among target expression, pathway activity, and response to a therapeutic agent.
   - *Are sufficient concentrations achieved in plasma, blood, and tissues?* Obviously, if for pharmacokinetic reasons adequate concentrations of the drug are not achieved in animal studies, or in patients in phase I studies, it is pointless to proceed forward with that particular drug structure.
   - *Is there activity on the desired molecular target?* For example it is common, when studying the activity of a particular kinase inhibitor, to assess the phosphorylation of a downstream substrate. Lack of activity on the target can be a reason for lack of therapeutic benefit, though it must be said that some of the new target-oriented therapies can lead to clinical benefit by apparently acting on targets (e.g. with similar ''active sites'') not previously foreseen or identified.
   - *Is there modulation on the desired molecular target?* It may be useful also to look at ''off-target effects,'' since the *in situ* regulatory feedback circuits can lead to unexpected biochemical changes.
   - *How can we achieve the desired biological effect?* For example, which regulatory pathway (cell cycle control, apoptosis, necrosis, etc.) is to be predominantly interfered with?
   - *Is a clinical benefit seen (in objective tumor response, growth inhibition, time to disease progression, survival)?*
   - *Finally, but very importantly, is the molecular target really key in the pathogenesis of that particular cancer?* If so, as seems to be the case, for example, for the abl-bcr fused genes in CML, or the EWS gene translocations and rearrangements observed in many human sarcomas, then hitting the target *per se* would have beneficial therapeutic consequences. Otherwise, only one target

will not be enough, and multitargeting will be required for good clinical efficacy.

8. Some form of dynamic and efficient (''parallel or sequential'') coordination of projects between Diagnostics and Pharmacology, and *vice versa*, is also highly desirable. Clinicians are already faced with increasing numbers of difficult therapeutic choices, and it would be naive to believe that this increasingly complex decision-making process will be based exclusively on simple classical clinical or pathological characteristics such as the age of the patient, performance status, TNM stage (which describes the degree of local or distant growth and spread of the tumor), and conventional histopathological degrees of differentiation (SBR in breast cancer, or Gleason score in prostate cancers).

Let us look, for example, at the present clinically complex situation in two very common cancers:

1. *Colon cancer*: The introduction into clinical practice of 5 new drugs – the cytotoxics Irinotecan and Oxaliplatin, the oral cytostatic Capecitabine, and the monoclonal antibodies Cetuximab (an antagonist of EGFR), and Bevacizumab (best described as an inhibitor of angiogenesis that ''traps'' VEGF) – , in addition to the old classic antimetabolite ''5-Fluorouracil,'' has dramatically increased the number of possible permutations and combinations of all active drugs in metastatic colon cancer to the extraordinary figure of 720 possible choices.
2. *Breast cancer*: A special case of targeted therapies is that of endocrine therapies for cancer, which actually constitute the first historical example of targeted therapies. For example, inhibition of estrogen (in breast cancers), or testosterone (in prostate cancers) action or production can probably be regarded as the first examples of anticancer-targeted therapies. Beatson first observed tumor regression of breast cancer in some patients following oophorectomy in 1896, but it was not until some 60 years later that estradiol receptors were identified by following the localization of radioactive estradiol in the immature rat. How hormones influence growth and behavior of malignant tissues was not known in those days, and even today a lot of questions remain unanswered.

Approximately two-thirds of all breast cancer patients have estrogen-receptor positivity in their tumor, and about half of them respond to endocrine therapy, at least initially. The reasons why the other half or so of patients with estrogen-receptor-positive tumors do not respond to endocrine therapies are rather complex and not completely understood.

Somewhat similarly, at least 80% of prostate cancer sufferers initially respond to androgen withdrawal, but regretfully the mean treatment response duration in prostate cancer is only about two years. Both types of endocrine therapy have both cytostatic and cytotoxic properties for cancer cells. Perhaps surprisingly, neither estrogen receptors (ER) nor androgen receptors (AR) have been described as proto-oncogenes, even though, at least theoretically, their mutation into activated forms could lead to some competitive advantage to affected cells. The truth is that, in contrast to the large numbers of missense AR mutations that have been found in association with androgen insensitivity syndromes, there do not seem to be many AR mutations that

predispose to human prostate cancer, with the exception perhaps of a missense mutation present in the germline of 0.33% of the Finnish population and 1.91% of Finnish prostate cancer patients.

For many years, Tamoxifen, a drug that binds the estrogen receptor with high affinity and that globally acts as a partial agonist/antagonist, was the only oral endocrine therapy available for most breast cancer patients, with estrogen-receptor positive tumors. Now, however, the emergence of several new antiestrogens (the so-called *Aromatase Inhibitors*, for example, of which three different molecules have already been approved for marketing), and some clinical studies suggesting that LHRH-agonists may be equally, or more, active than conventional low-intensity chemotherapy (like CMF) as adjuvant therapy in young premenopausal women, has made decision-making algorithms significantly more complex for both clinical oncologists and breast cancer patients.

For example, as recently reviewed by Hortobagyi, with regard to conventional cytotoxic chemotherapy for breast cancer we have gradually learnt, over more than three decades of work, that the use of CMF (cyclophosphamide, methotrexate, and 5-FU) as ''adjuvant chemotherapy,'' following primary breast surgery (to treat potential microscopic residual or metastatic disease), can reduce the odds of cancer recurrence by some 23.5%, and of cancer-related death by 17%. The use of anthracycline-containing regimens, though usually more toxic and associated with iatrogenic hair loss (alopecia) and potential cardiotoxicity, improves results by another 11 and 12% for odds of recurrence and death, respectively. Finally, the introduction of taxanes (that alter microtubular assembly in dividing cells, among many other biochemical changes) in addition to anthracyclines may result in a relative reduction in odds of recurrence, compared with no adjuvant systemic therapy, of some 40 to 60%, depending on age and hormonal status of the patient.

If tamoxifen, the partial agonist/antagonist of estrogen, is used alone as adjuvant therapy in postmenopausal women with estrogen-receptor postive breast cancers, a five years duration of treatment implies a reduction in the risk of local cancer relapse of close to 47%, and an impressive 26% reduction in the risk of cancer-related risks. A more recent large study, conducted by the National Cancer Institute of Canada, has shown that if five years of Tamoxifen, in a premenopausal estrogen-receptor-positive group of breast cancer patients, are followed by five years of an oral aromatase inhibitor called ''Petrozole'' (that effectively acts as a peripheral ''antiestrogen''), the risk of local relapse of cancer is reduced by between 43 to 53%, depending on axillary lymph node status, with a 46% reduction in the risk of contralateral breast cancers, and a fairly significant increase in disease-free interval (and perhaps overall survival), as compared with the group of patients receiving tamoxifen alone.

To make matters even more complicated on the subject of hormonal treatments of breast cancers, a recent study with a different aromatase inhibitor (exemestane) has shown that three years of tamoxifen followed by two or three years of exemestane, produces better clinical results than the conventional five years of adjuvant Tamoxifen.

Bearing in mind these results and other considerations, even nonclinicians will easily understand why explaining the various treatment options to cancer patients and relatives, together with

adequate explanations on primary treatments, like the radical surgical approach (e.g. mastectomy), *versus* the conservative (e.g. ''tumorectomy plus radiotherapy'') approaches, or the new ''sentinel node'' technologies (e.g. to spare radical axillary lymph node dissection), tend to occupy increasing amounts of time during the initial clinical consultation, and are becoming one of the most difficult tasks for all clinical oncologists.

Conclusion on the threats Unless we find new and more efficient (faster and less expensive) ways to develop new anticancer drugs, and new and more rational (as well as more practical) criteria for using them in combination, the majority of health systems will simply be unable to cope with the expected ''avalanche'' of new medications.

Professionals will soon be in difficulty when deciding on which combination of drugs to use in any given patient, and in exactly which combination or sequence. Patients themselves (gradually better informed, and naturally keen to actively participate in the therapeutic decision process) will become more confused, and perhaps more vulnerable to biased information or misinformation; and, last but not least, many, if not most health providers may eventually be unable to pay for all new drugs and procedures, considering the ever-increasing costs.

If we also add the rapid demographic changes (that lead to an elderly population with many more cancers) in the developed world, and the increasing political pressure to control pharmacy costs, we come to the inevitable conclusion that dealing with the cancer problem is bound to get initially more complex and expensive, before it becomes rationally more manageable and less expensive.

Molecular Oncology has a lot to do with all this, both as a partial cause of the problem, and as a possible rational solution in the mid- to long-term.

More should probably also be spent on prevention/early detection, and research on ''chemoprevention.'' Thus, health authorities may soon ask themselves whether it makes sense to increase by 20to 40% the overall costs of treating, for example, metastatic colon cancer or advanced lung cancers, to gain only a year or less of overall survival, rather than adopting more aggressive policies to induce people to undergo more regular colonoscopies,, under sedation, from the age of 50 (say, three times in a lifetime, at 50, 60, and 70 years of age, in the absence of high risk factors) or to simply quit smoking.

The case of AIDS is a good example. Besides a better general knowledge and control of risk factors in the populations at risk, at least within the developed world, the introduction into the clinic, well over a decade ago, of ''expensive'' combinations of new antiretroviral oral therapies has dramatically increased the life expectancy of HIV-infected cases, from 3 to 5 years at first, to an almost normal life expectancy or, in any case, well over 15 years of life. In this case, chronic expensive therapies ''make sense,'' and are easily justifiable, even to the most rigorous and cost-conscious public health systems. Even under these favorable circumstances, given the fact that the HIV retrovirus in most infected patients often produces several mutant molecular forms each day, the problem of drug resistance remains. This justifies the molecular sequencing of the genome of HIV mutants and, based on the genetic variations detected, changing the individual medication to other suitable antiretroviral drugs, or putting the patient into new drug testing programs.

4.1.2 Opportunities

1. The activity of many of the cytotoxic agents used in clinical practice today was first detected by traditional screening methods, as in the case of murine leukemias (L1210 and P388) and murine solid tumors. But these cytotoxic drugs were essentially designed to interfere with DNA or chromosomal replication, because we were ignorant of the molecular basis of cancer.
2. As explained in this chapter, we are beginning to have enough information on the precise molecular mechanisms involved in the regulation of ''cell behavior'' (benign or malignant), and we shall soon be prepared to classify all the ''players'' (regulatory proteins) into ''processes'' (regulatory pathways in disease).
3. It is now possible not only to tell which are the key players in each pathway, but also how each pathway is organized (from upstream to downstream), and where we should intervene therapeutically to correct the malignant behavior of tumor cells (e.g. inhibiting angiogenesis, cell growth or the metastatic process), or to eradicate malignant cell clones (by facilitating senescence and/or apoptosis, or by stimulating the destruction of tumor cells).
4. In simplistic terms (see Fig. 3 for graphic explanation) the new therapeutic drugs should either:
   - block or inhibit activated proto-oncogenes in their inactive state, like Gleevec in the case of several Tyrosine Kinases, for example; or
   - considering the fact that most regulatory molecules have binary states (active/inactive), somehow lock or stabilize tumor suppressor proteins in their active state, which is the one normally responsible for inhibiting entry into S-phase or mitosis, and for maintaining the normal differentiation and apoptotic pathways.
5. In other words, as regulatory proteins are usually present in normal cells in either an active form or inactive form, and the chemical equilibrium between the two forms depends on the regulatory microenvironment of the cell, new targeted therapies should be able to correct, or at least limit, the malignant phenotype by restoring the normal balance between stimulatory and inhibitory signals within the cell.
6. Examples of these new types of ''oncogene inhibitors'' drugs are either already on the market (e.g. Gleevec or Herceptin), or in development (EGFR inhibitors, VEGF inhibitors).

   The case of tumor suppressor genes is more complex, because the ideal therapy in these cases, where the problem is usually a loss-of-function mutation of the promoter (e.g. a deletion or a hypermethylation), would be a genetic replacement of the wild type. However, because of mainly technical reasons (lack of suitable vector, inefficiency of the transformation systems, lack of stability of ''transfected cells,'' danger of oncogenetic transformation by retroviruses, etc.), the truth is that the original research enthusiasm of the 1990s regarding the clinical therapeutic application of genetic therapy programs no longer exists, even if new approaches and new techniques are under active investigation. However, as I postulated in the Second Edition of ''Principles of Molecular Oncology'' (Humana Press, N.J., 2004) and also in this article, there is a possibility of developing low-molecular-weight

drugs capable of inhibiting the ''inactivation of tumor suppressor function,'' for example, inhibitors of Rb phosphorylation or activating ''cryptic'' tumor suppressor functions.

Because of the presence of either wild-type or mutant p53 protein in most human tumors, the restoration of endogenous p53 function in cancer cells by small-molecular-weight compounds (as shown by Bykov et al, 2002), or by the *in vivo* delivery of transducible, proteolytically stable p53C' d-peptides such as RI-TATp53C' (as recently shown by Snyder et al, 2004) have become promising new approaches to cancer therapy.

7. In this way, we can hope to eventually reduce the number of potential therapeutic targets from several hundreds to perhaps only twenty or thirty major primary targets. Most of these processes, if not all, will have upstream regulatory elements (e.g. membrane-bound or membrane-associated), intermediate elements (cytosolic or bound to organelles, like mitochondria) and downstream elements (transcription factors, DNA- or RNA-specific sequences). A critical and exciting phase will be the development of models based on the abnormal circuitry of regulatory pathways in cancer cells. This would help us to find the ''Achilles heel'' of the particular cancer (Weinstein, 2002), or the right combination of targets to tackle.

The main targets for cancer therapy identified so far can be summarized as follows:

Angiogenesis Biological process that leads to the formation of new blood vessels, and that involve the proliferation of endothelial cells and their morphological association into functional capillaries. The ''angiogenesis switch'' refers to the set of changes in gene expression and protein function that can change the natural local tissue balance between ''inducers and inhibitors of angiogenesis,'' for example, secretion of growth factors like FGF (Fibroblast Growth Factors) or VEGF (Vascular Endothelial Growth Factors), or changes in membrane receptors associated with the malignant invasive phenotype and growth of tumors.

Hypoxia-inducible factors (HIF), cytokines, cellular adhesion molecules (CAMS) like the Integrins family, or secreted proteases like the metalloproteinases (MMPs) can also alter the angiogenic phenotype of tissues.

A great variety of molecules produced by normal mammalian cells can inhibit angiogenesis, such as thrombospondin, angiostatin, endostatin, tumstatin, arresten, and vasostatin. Of the approximately 200 compounds with antiangiogenic activity described so far, several are already in clinical testing, but we are only really beginning to unravel the complexities of the subject, particularly in humans.

One of the most promising approaches is the use of humanized monoclonal antibodies with the capacity to inhibit binding of VEGF to its receptor, or other inhibitors of VEGFR activation. VEGF-A is a highly specific, selective mitogen for vascular endothelial cells *in vitro*, and is produced *in vivo* by many tissues.

For example, Bevacizumab, a humanized monoclonal antibody against VEGF, has already shown reasonably good results in clinical testing up to phase II and phase III studies. It has shown modest activity in breast cancer, but significant prolongation of the time to progression of disease in metastatic renal cancer and, when added to

cytotoxic chemotherapy, it significantly improved survival in patients with metastatic colorectal cancers.

Antiangiogenic therapies would no doubt be ideal adjuncts, or complementary long-term therapies, to primary surgical treatments or to chemo-radiotherapy programs. They should also reduce the problems of resistant phenotypes, considering that these new endothelial cells are normal, and have genomic stability.

''Angiolytic'' substances such as Adherins and Integrins, which are inhibitors of the function of several cellular adhesion molecules, are also under investigation. In principle, they are capable of disrupting preexisting tumor blood vessels *in vivo*, thereby leading to interruption of the blood supply, and necrosis of the tumors.

Apoptosis Apoptosis is a biological process that describes the complex mechanisms of ''programed cell death,'' eventually leading to endonuclease driven fragmentation of DNA and chromatin by a number of Caspase-dependent or Caspase-independent biochemical events. Although the mitochondrial release of cytochrome-C appears essential for at least some caspase-mediated events, mitochondrial-independent activation of caspases *via* activation of the Fas-FasLigand pathways (also known as CD95, or APO-1 pathways) is also reasonably well defined. The mitochondria are currently seen as an important convergence point for a number of pro-apoptotic or antiapoptotic members of the so-called *Bcl-2* family of proteins. However, the recent enthusiasm for ''apoptosis'' as the main, or only, mechanism of tumor cell death can be prudently questioned on several grounds. Except in cells of lymphoid origin, apoptosis is a relatively insignificant mode of cell death for most cells in solid tissues, and experimental conclusions based on measuring the extent of cell kill by cytotoxic agents, rather than on true effects on clonogenic survival of tumor cells, can be misleading. Thus, despite the seemingly strong case that cells die from cancer treatments (chemotherapy or radiotherapy) because of apoptosis chiefly controlled by wild-type p53, much current data do not appear to fit with this simple hypothesis. On the other hand, it seems reasonable to expect that unless new drugs are capable of inducing cell death (by necrosis or apoptosis), the therapeutic effects will be mainly ''cytostatic'' rather than ''cytotoxic.''

Clinicians, and patients of course, like to see tumors ''shrink'' or, ideally, to ''disappear,'' rather than just stay ''more or less the same,'' with ''stabilization'', that is, no clear tumor growth but no tumor size reduction either.

Binary state (of regulatory molecules) In ancient Chinese philosophy and medicine, the Universe we live in was clearly a model of the binary nature of things. For example, ''cold'' was considered to be a ''Yin'' pathogenic factor, and its nature is to slow things down. On the other hand, ''heat or fire'' was considered a ''Yang'' pathogenic factor, causing expansion and increased activity. In a similar sort of way, all biochemical regulatory proteins can be present at any one time in an ''on'' or ''off'' molecular form, with regard to one or more of their functions.

This ''Yin'' or ''Yang'' effect will depend, for the normal wild-type forms of regulatory proteins, on the regulatory microenvironment, and the possible conformational changes (usually allosteric) produced by a number of enzyme activities including phosphorylation/dephosphorylation, acetylation/deacetylation, farnesylation/

defarnesylation, methylation/demethylation, and so on.

Cell Cycle Checkpoints: Mammalian cells can remain quiescent (in Go phase of their cell cycle) for long periods of time, but the right combination of growth factors can induce them to enter G1 and then, if no impediment occurs, progress through S-phase (DNA replication), G2, and mitosis, and complete their cell division. Tumor doubling times can show tremendous variations. For example, some 60% of human breast cancers show tritriated thymidine incorporation rates and labeling indices of less than 4%, indicating a rather slow doubling time of tumor cells, but the rest of the breast cancers can show labeling indices between 4 and 41%. No doubt this reflects the molecular heterogeneity of breast cancers. The best and more selective anticancer drugs of the future, in this cell cycle setting, would have to tag specific cyclins (e.g. cyclin D1 and cyclin E, that can act as *de facto* potent oncogenes) for degradation. Recent research points towards a key role for Cyclin E in breast cancer, and Cyclin D1 in some non-Hodgkin's lymphomas and in colon cancer, where they act as potent oncogenes. Alternatively, marked cytostatic effects should be produced by new drugs designed to stimulate the activity of selective CKIs (Cyclin-dependent kinase inhibitors), or to lock crucial downstream elements (like the retinoblastoma protein complex) that act as *de facto* tumor suppressor genes, in order to enable them to maintain their active roles as cell cycle inhibitors.

Cell shape Surprisingly little systematic research has been published to establish the molecular links between ''cell shape'' and ''cell behavior.'' Yet it makes sense to assume that both are related. For example, most differentiated epithelial cells adopt a rectangular or polygonal shape, and display a marked polarity (from their attachment to the basement membrane, to the opposite membrane surface on the lumen), as well as a solid cytoskeleton, parallel anchorage to neighboring cells, abundant cytoplasm and endoplasmic reticulum, and low, if any, migration capacity. They also display a low rate of proliferation (except at special sites like the intestinal crypts, where they change shape anyway). In general, as cells take a spindle shape (epithelial-mesenchymal transition, or *vice versa*), they become more potentially mobile and proliferative. Finally, blood cells tend to be round, with a high nuclear/cytoplasm ratio, and are both more mobile and more likely to undergo cell division if stimulated.

The so-called *blast cells*, in leukemias and lymphomas, and also in undifferentiated or poorly differentiated carcinomas, show similar changes in shape, nuclear/cytoplasmic ratio, mobility, and high- proliferative activity.

Downregulation of ''adherens junctions'' (AJ) assembly by mutations, hypermethylation, or transcriptional repression of the adhesion molecule E-Cadherin, have been described in several malignancies, and particularly in human diffuse gastric carcinomas, lobular breast cancers and familial gastric cancers. In many ways, E-cadherin behaves as a tumor suppressor gene, while *beta*-catenin behaves as a potentially potent oncogene. Thus, when the ratio of free cytoplasmic *beta*-catenin is too high, because (for example) of loss of E-cadherin, or because of APC mutations, an excess of *beta*-catenin is free to travel to the nucleus. This leads to the overexpression of a set of transcription factors (TCF/LEF), and of potent oncogenes such as cyclin D1 or c-myc.

When the intracellular levels of another important protein regulator (named *snail*) rise above a certain threshold, there is usually active repression of the transcription of the *E-cadherin* gene, and a promotion of the so-called *epithelial-mesenchymal transition* (*EMT*), that leads polygonal/epithelioid-shaped cells to convert into spindle/round type of cells.

Chemoprevention Chemoprevention is ''the treatment of carcinogenesis, its prevention, inhibition or reversal.'' The term ''chemoprevention'' is controversial. Some may confuse the term ''chemo'' with ''chemotherapy'', and ''prevention'' may not be the best word to define ''early detection'' of cancer biomarkers. The subject is bound to grow very rapidly, both in terms of the identification, validation, and clinical relevance of cancer biomarkers, and also in terms of their impact on the quantitative estimation and prediction of individual human cancer risks.

In the relatively recent past, the possibility has been raised that pharmacological agents or nutritional modification might prevent the development of human cancer, or at least slow down its progression. The concept of chemoprevention is gaining support, although there are still significant experimental and conceptual problems associated with it. For example, if the study population is composed of normal or nearly normal subjects (such as normal volunteers, smokers without obvious disease, or people with a history of one isolated gastrointestinal polyp), very few side effects may be acceptable. In contrast, if the subjects are at high risk of cancer (e.g. have a history of familial polyposis, hereditary predisposition to breast or colon cancer, or second tumors) considerable side effects may be acceptable.

It remains possible that many of the target-oriented new drugs being developed will show clinically relevant efficacy in cancer chemoprevention studies, perhaps even superior to that shown in advanced cancers. The reason is that these target-oriented new drugs usually display tolerable or little toxicity, can be administered orally for long periods of time, and delay the growth of cell clones with a proliferative or angiogenic advantage over their normal counterparts (e.g. by interfering with growth factor signal transduction, or with the angiogenic process).

There is also significant scientific interest in certain metabolic or detoxification phenotypes that may lead to a higher cancer risk, such as aryl hydrocarbon hydroxylase activity (AHH), debrisoquine hydroxylation, and glutathione-S-transferase activity. For example, AHH activity depends on one subfamily of cytochrome P-450 microsomal enzymes that convert polycyclic aromatic hydrocarbons into carcinogenic intermediates. Case-control studies have yielded contradictory results regarding the association between AHH activity in lymphocytes and lung cancer risk. Why only a minority of heavy smokers actually develop lung cancer remains largely unknown.

Beta-carotene, the retinoids, folic acid, vitamins C and E, and tamoxifen have been reported so far in published phase III clinical chemoprevention trials. The retinoids have probably been studied the longest and, although their therapeutic index is somewhat narrow because of toxicities, they have achieved successful results in oral leukoplakia, actinic keratosis, prevention of skin cancer in xeroderma pigmentosum, and prevention of second primary tumors in squamous cell carcinoma of the head and neck. More recent, but rapidly growing, is the role of other agents, such

as cyclooxygenase-two (COX-2) inhibitors in chemoprevention. COX-2, a key enzyme for the production of prostaglandins from arachidonic acid, is overexpressed in colon carcinogenesis and other malignancies.

The role of tamoxifen in chemoprevention of breast cancer has recently reached the front pages of newspapers. A recent report from the American Society of Clinical Oncology (ASCO) lists several conclusions endorsed by the Health Services Research Committee and the ASCO Board of Directors. Tamoxifen, at 20 mg/d for 5 years, may be offered to reduce the risk to women who have a defined breast cancer risk of more than or equal to 1.66%. Risk/benefit models suggest that greatest clinical benefit with least side effects is derived from the use of Tamoxifen in younger premenopausal women who are less likely to suffer thromboembolic sequelae and uterine cancers. Data confirm a substantial reduction in breast cancer risk, but do not yet demonstrate, probably because of a relatively short follow-up, an overall health benefit or increased survival. Tamoxifen is not free from side effects but health-related quality of life is not adversely affected in most cases.

Drug resistance Conventional cytotoxic chemotherapy and radiotherapy were designed to hit the DNA synthetic machinery of rapidly proliferating cells, to alter the integrity of DNA in tumor cells, or to interfere with microtubule assembly and chromosomal movements during mitosis. With these rather nonspecific forms of therapy, some relatively uncommon cancers, like many pediatric tumors, some leukemias and lymphomas, germ cell cancers, and a few other malignancies can be totally cured. And in many other cases, although these therapies do not offer much hope of cure, they can nevertheless provide effective palliation of symptoms, and even (when used as adjuncts to primary surgical resection) increased overall survival, or at least disease-free interval. Although the judicious use of these agents, together with surgical treatments, remains the mainstay of Oncology Therapeutics, their success in curing or totally eradicating the majority of the most common cancers is limited, and usually inversely proportional to the total amount of cancer cells, among other important prognostic factors.

Surprisingly, conventional chemotherapy and radiotherapy work not because cancer cells are especially more ''sensitive'' to their cytotoxic effects than normal cells, but because normal cells usually can recover faster and more efficiently than cancer cells. Normal tissues virtually never develop resistance to chemotherapy, probably because they maintain the mechanisms that allow normal renewing cell populations, like the highly proliferating cells in the normal bone marrow or gastrointestinal tract, and are capable of monitoring and correctly repairing DNA damage, or induce the programed cell death (suicide) of cells with irreparable DNA damage. Unfortunately, many cancer cells that have lost these normal repair mechanisms become resistant to the action of cytotoxic treatments. In 1943, Luria and Delbruck observed that the bacterium *E.coli* developed resistance to bacterial viruses (bacteriophages), not by surviving exposure, but by expanding clones of bacteria that had spontaneously mutated to a type inherently resistant to phage infection. In other words, following a process of Darwinian selection, those clones inherently resistant to the killer phage gradually outgrow the rest of clones when exposed to the killer agent. On the basis of this model, Goldie and Coldman proposed, in 1979, a model that predicted that cancer

cells mutate to drug resistance at a rate intrinsic to the genetic instability of a particular tumor. A large number of potential drug-resistance mechanisms have already been described. Some refer to the existence of multidrug resistance proteins (like the so-called *P-glycoprotein*) on the cell membranes of some cancer cells, and even normal cells of certain tissue types. These proteins can actually actively pump cytotoxic agents out of cells. Others refer to specific mechanisms of resistance unique to each cytotoxic agent. But the predominating general opinion today is that the main mechanisms of resistance to current cytotoxic therapies are more general and, as already described above, more linked to the particular set or combination of genetic and epigenetic defects in DNA-repair pathways, cell cycle control pathways and apoptosis, than to the specific molecular structure of the cytotoxic drug in question.

Growth factors These were defined in the 1970s, long before their molecular characterization and purification, as substances other than nutrients required by cells *in vitro* for their survival, proliferation, and differentiation.

In fact, it was soon discovered that normal cells are simply unable to survive and grow *in vitro* except in the presence of serum, and fetal calf serum became the 'gold standard' critical component for culture medium. Only some transformed cells, or cancer-derived cell lines, as shown by seminal work by authors like Sporn and Todaro(1980) and Sporn and Roberts (1985), were capable of growing in serum-free medium, because these transformed cells either produce their own growth factors (''autocrine'' stimulation), or had become ''growth factor-independent'' because of the activity of Oncogenes and the lack of activity of tumor suppressor genes.

Substantial evidence, derived from the use of recombinant growth factors *in vivo* (growth factors produced by molecular cloning, and expression of the gene product by a suitable recombinant vector), or from experiments with transgenic animals or site-directed mutagenesis, supports the notion that these substances serve similar purposes *in vivo*. Therefore, it is now widely accepted that differentiation, proliferation, and survival of most normal tissue types is controlled, at least in part, by a complex network of regulatory growth factors. These are usually glycoproteins, frequently of low molecular weight, that act at very low concentrations, in the picomolar range, by binding to specific cell membrane receptors. These receptors can be present in both high-affinity and low-affinity forms, they can be absolutely specific for one growth factor or be shared by two or more factors, and they can be membrane-bound, soluble or both. Some signaling systems, like the Wnt, depend also on the combined activity or modulation of membrane-bound ''coreceptors.'' It has been suggested that HER-2 is also a ''coreceptor.''

Unlike conventional hormones, which are produced by specialized glands, most growth factors appear to be made systemically; stromal cells (e.g. fibroblasts or endothelial cells), inflammatory cells (e.g. macrophages), and activated T-lymphocytes are some of their main sources. Some perhaps surprising findings regarding the production and secretion of specific growth factors, point to the kidney as being the main physiological producer of erythropoietin (that stimulates the production of red blood cells), and the liver as the main physiological producer of thrombopoietin, also called *MGDF* (*megakaryocyte growth and differentiation factor*), a key regulatory molecule in the production of platelet precursors.

Most standard conventional chemotherapy protocols were designed based on the kinetics of recovery of the bone marrow in response to cytotoxic agents, because neutropenia and thrombocytopenia can easily become doselimiting. The successful introduction into clinical practice (in the mid-1980s) of recombinant human colony-stimulating factors, such as G-CSF (Granulocyte Colony-stimulating Factor, or Filgrastim) and GM-CSF (Granulocyte-Macrophage Colony-stimulating Factor, or Sargramostim), led to a marked decreased in iatrogenic morbidity and mortality.

The use of recombinant human colony-stimulating factors has, according to Chu and DeVita Jr (2002) revolutionized chemotherapy treatments, by playing an important role in decreasing the incidence of infections and the need for hospitalization, and in enabling the maintenance of the optimal dose intensity of chemotherapy treatments for chemosensitive malignancies.

Most human growth factors are ''pleiotropic.'' That is to say, they can modify several cell types and several key regulatory pathways at once, rather than being absolutely cell-type-specific, and display some degree of ''redundancy.'' For example, even in the absence (in experimental animal systems like gene knockout mice) of highly cell-type-specific growth factors like the erythropoietin gene (*EPO*) or the granulocyte colony-stimulating factor genes (*G-CSF*), these gene-deficient animals can still survive with background production of endogenous red blood cells (normally driven by *EPO*), and/or white blood cells (normally driven by *G-CSF*).

It would be over-optimistic to expect growth factor inhibitors alone to prove to be highly effective anticancer agents. On the other hand, the combination of growth factor inhibitors and conventional cytotoxics, or other inhibitors of key signal transduction pathways, might prove valid as human anticancer therapies.

Intraepithelial neoplasia Intraepithelial neoplasia (IEN) is characterized as a moderate to severe dysplasia that occurs on the carcinogenic pathway from normal tissue to malignant cancers. Accumulation of genetic and epigenetic lesions results in the typical phenotypic changes associated with cancer cells, including loss of cell cycle control points, defects in DNA repair, aberrant methylation patterns, and defects in the apoptosis pathways. Because this process of carcinogenesis often requires many years, and most of the common epithelial human cancers increase in frequency, at times almost exponentially, from the age of 45 to 55 to old age, identification of IEN by histopathological or molecular means (genomics or proteomics analysis) can offer a window of opportunity for intervention in the progression of the malignancy.

Clinical studies for the early detection, and primary or secondary prevention of cancer (chemoprevention) are already ongoing for bladder cancers, breast cancers, cervical cancers, colon cancers, endometrial cancers, esophageal cancers, lung cancers, ovarian cancers, prostate cancers, skin cancers, and so on.

Oncogenes These are growth control genes that are present in the human genome (as ''proto-oncogenes''), as well as in the genomes of most, if not all, multicellular organisms. Incorrect expression or mutation of an oncogene usually results in gain of function and unregulated cell growth, as seen in malignant cells. Many of them are part of the complex cell's signal transduction pathways, including cell membrane growth factor

receptors, or intracytoplasmic proteins. These signal proteins may be an intracytoplasmic piece of the receptor molecule, or another molecule activated just inside the membrane. Tyrosine kinase is an example of a signal molecule. The first signal may serve only as an intermediary, affecting a change in a second messenger. The G proteins, for example (belonging to the *Ras* oncogene family) are a group of intracytoplasmic second-messenger molecules. The intracellular cascade of signals eventually reaches the nucleus, leading to changes in gene expression and cell behavior. Of the over 100 oncogenes that have been identified so far, most are key players in these signal transduction pathways.

Mutations The molecular changes in DNA associated with carcinogenesis are not very different from those associated with genetic variation and molecular evolution of organisms and species, and include local changes in DNA sequences, rearrangement of DNA segments within the genome, and (in the case of viral carcinogenesis) horizontal transfer of a DNA (or RNA) segment originating in another kind of organism.

Basic definitions of these three different natural strategies that allow for genetic variations have been explained in detail in this same Encyclopedia by the Nobel Laureate Werner Arber (Biozentrum, University of Basel).

Point mutation, for example, means the replacement of a single correct nucleotide within a gene by an incorrect one, and can occur as a result of one of several mutagenic events. Mutagenic chemicals (e.g. from cigarette smoking) enter the cell and bind to DNA, forming a structure called a *DNA adduct* which, during replication of the DNA molecule, will lead to an incorrect nucleotide substitution.

Mutagenic chemicals can damage DNA in many other ways, such as by methylation of a nucleotide. Radiation can cause single strand breaks. In general, it is thought that most, but not all, carcinogens are mutagenic. In contrast, the so-called *Tumor Promoters* are substances that by themselves do not cause mutagenic events, but amplify, directly or indirectly, preexisting cellular clones with mutations.

There are at least 16 ways to reduce or abolish the function of a gene product: delete the entire gene, ensure loss of the relevant chromosome, delete part of the gene, disrupt the gene structure (by a translocation or an inversion), insert a sequence into the gene, inhibit or prevent transcription, promoter mutation reducing mRNA levels, decrease mRNA stability, inactivate donor splice sites (causing read-through into intron), inactivate donor or acceptor splice sites (causing exon to be skipped), activate cryptic splice sites, introduce a frameshift in translation, convert a codon into a stop codon, replace an essential aminoacid, prevent posttranscriptional processing, or prevent correct cellular localization of product. Mutation of a gene is not the only way to abolish its function (e.g. long-range chromatin alterations, abnormal methylation and/or imprinting). For example, in human neoplasms *p16* is silenced in at least three ways: homozygous deletion, methylation of the promoter, and point mutation. The first two represent the majority of inactivation events in most primary cancers. *P16* is a very common early event in cancer progression and is frequently seen in premalignant lesions. The importance of *p16* is probably similar to that of *p53*. Mutations in the *p53* gene have been found in

some 30% of human tumors, and wild-type *p53* has been reported to suppress tumorigenesis and promote apoptosis (236). The p53 protein is a potent transcription factor and may promote transcription of genes that are also involved in carcinogenesis and angiogenesis.

Loss-of-function mutations usually produce recessive phenotypes, so that as long as one allele remains normal there are no significant phenotypic changes. However, for a limited number of genes, a 50% reduction in the dosage of the gene can lead to phenotypic changes (dosage effect). Certain regulatory functions are inherently dosage-sensitive: for example, gene products which compete with each other to determine a developmental or metabolic switch, or that cooperate with each other in interactions with fixed stoichiometry, or those whose function depends on partial or variable occupancy of a receptor or DNA binding site.

Less frequently, mutations can lead to gain-of-function, rather than loss-of-function. For example, they can result in the ability to acquire a new substrate, overexpression of the gene product, the receptor being turned permanently 'on', the ion channel being inappropriately open, structurally abnormal multimers, chimeric gene, the ability to bind to new DNA sequences, or the ability to trap and inactivate important regulatory molecules. If a protein has several catalytic and allosteric domains (e.g. at a regulatory network bottleneck), destruction or loss-of-function of only one of these domains can allow others to be inappropriately activated.

It is, at least theoretically, possible that some carcinogenic events may include both loss of the natural function of the gene product, and gain of a function not normally associated with that particular gene product. For example, a truncated protein might be unable to perform the original function of the native protein, but could still interact functionally with other regulatory proteins by exposing the remaining protein domains.

Proteasomes The average human cell contains about 30 000 proteasomes, each of which contains several protein-digesting proteases. These complexes help regulate a variety of important cellular functions besides the cell cycle, such as the response to viral infection, the so-called *"stress responses,"* abnormal protein catabolism, neural and muscular degeneration, antigen processing, DNA repair, and even cellular differentiation. In fact, at least in principle, diseases can develop if the system is either overactive or underachieving. This research field is rapidly evolving, and a number of proteasome inhibitors are now under development. In fact, at least one of them (Bortezomib) has already been approved by the FDA for the clinical treatment of refractory multiple myelomas.

When the cell needs to destroy a protein, it usually marks it with a chain of small polypeptides called *ubiquitin*. The ubiquitin–proteasome pathway degrades 90% of all abnormal, misfolded proteins, and all of the short-lived regulatory proteins in the cell. These short-lived proteins, whose half-lives are less than three hours, account for 10 to 20% of all cellular proteins. As a result, proteasome inhibitors do not target individual cellular functions, but they usually affect a broad spectrum of functions.

The research area that has evolved fairly rapidly in recent years is that of the so-called *Ubiquitin-Proteasome Pathways*. This involves the processes of selective intracellular protein degradation. For example, the intracellular levels of cyclins, proteins

required for cell cycling, are strictly controlled, and seem to be crucial for the normal functioning of several regulatory cell cycle checkpoints. Indeed, the activity of cyclins appears to be mainly regulated by cyclin levels, rather than by intrinsic molecular changes. Cyclin-dependent Kinase Inhibitor(CKI) protein levels are also strictly controlled throughout the cell cycle, and their degradation is also dependent on the ubiquitin-proteasome pathways.

At least theoretically, selective degradation of cyclins (that often act as oncogenes) but selective inhibition of degradation of CKIs (like *p16* or *p27*, that act as tumor suppressor genes) would provide cancer clinicians with new and powerful tools to fight cancer cells.

The overall regulatory process is rather complex. For example, in normal proliferating cells, the *CKI p27* is actively degraded. The ubiquitin-conjugating enzyme Cdc34, which is a ubiquitin ligase (formed of at least four subunits: the F-box protein Skp2, Skp1, Cul1 and Roc1), and Cks1 are required for the transfer of ubiquitin to phosphorylated *p27*. In a self-amplification process, CDKs phosphorylate *p27* on Thr 187, allowing *p27* recognition by the Skp2 subunit of the ubiquitin ligase.

Stromal cells and cancer Stromal cells are all those cells in a tumor that are not cancer cells. They form the tumor microenvironment and, unlike tumor cells (which are usually monoclonal), they are polyclonal, and contain a mixture of mesenchymal cells (fibroblasts, for example), inflammatory cells (macrophages), immune cells (lymphocytes), antigen-presenting cells (dendritic cells), and other circumstantial cell types. The tumor microenvironment is extremely important for cancer growth, and often it represents the end-result of a perverse gradual mechanism of invasion and destruction by the mutated cancer cells (the ''evil terrorists'') of the tissues of the host (or ''victim'').

In other words, cancer cells often direct themselves the building of the stromal cell tissue microenvironment, in order to allow an even better growth advantage over normal cells, to evade any possible immune resistance, and to continue their invasion of normal structures.

One illustrative example of the sophisticated mechanisms that can lead to normal tissue destruction by cancer cells is the formation of osteolytic lesions in multiple myeloma. Multiple myelomas are a class of cancer cells derived from precursors of B-cell lymphocytes. They are usually diagnosed by detecting abnormally high-monoclonal serum levels of an immunoglobulin (heavy or light chains, or both, of any type), associated with an increase in plasma cells within the bone marrow, of different degrees of morphological differentiation. They can be localized to one site, but more often they are already disseminated in multiple sites at the time of clinical presentation. Although they are usually more frequent in old age, they can also affect young people. The associated symptoms are difficult to control clinically, because multiple myelomas can lead to multiple osteolytic lesions (''holes'' in the bones), generalized loss of bone density, pathological bone fractures, and insufficient hemopoiesis (blood production). These conditions produce a tendency to develop infections because of immune suppression (reduced levels of protective immunoglobulins and normal white blood cells), and bleeding problems (because of the reduced levels of platelets). Myelomas are usually treatable (but seldom curable), by a combination of chemotherapy, radiotherapy, and intravenous biphosphonates,

that are potent inhibitors of osteoclastic activation.

Some recent work has suggested that myeloma cancer cells modify the normal and dynamic ''yin and yang,'' of bone formation (e.g. osteoblast function) and destruction (osteoclast function). The cancer cells achieve this by, among other mechanisms, secreting RANKL (receptor activator of nuclear factor-kB ligand), a potent stimulator of osteoclast function, and by increasing the degradation of 'Osteoprotegerin', the natural soluble antagonist of RANKL.

Furthermore, Tian and colleagues, by comparing different patterns of gene expression in 57 of approximately 10 000 genes in two subsets of myeloma patients (those with focal osteolytic lesions in bone, and those without), have recently demonstrated that some myeloma cells also secrete a soluble molecule called *DKK1*, that binds to an important class of growth factor ''coreceptors'' that can affect the Wnt-signaling pathway, resulting in decreased activity of osteoblasts. This might explain the loss of bone density in patients, and why normal osteoblasts in myeloma patients do not fill (with new bone) the ''holes'' made by myeloma cells themselves, or by their secreted pro-osteolytic substances.

A potential therapeutic approach to ameliorating the bone-specific morbidity of multiple myeloma is by the administration of a suitable antibody against DKK1. The development of new inhibitors of RANKL would also prove useful. In this way, the molecular approach would help toward the restoration of the normal microenvironment.

Tumor antigens They can be defined as molecules that contain the epitope determinants recognized by Tcells that specifically target tumor cells. For many years the underlying principle of tumor immunologists was that cells of the immune system can normally recognize tumors as distinct from the normal tissues (nonself), or as a danger to the organism, and eliminate them (concept of ''immunosurveillance''). Although it has now been clearly shown that many, but probably not all, tumors (for example, melanomas) display ''tumor antigens'', as discrete molecular entities, various mechanisms have been implicated in the resistance of tumors to immune attack: modulation of NK (natural killer cells) receptors, secretion of inhibitory cytokines, recruitment of accessory cells that may thwart immune function, downregulation of molecules critical for antigen-presentation, costimulation of immune cells, and so on.

All these potential mechanisms, and others, can lead to 'tumor editing', so that it is no longer recognized by the normal immune system as 'foreign' and therefore dangerous.

Tumor suppressor genes Unlike oncogenes, Tumor suppressor genes (formerly ''antioncogenes'') display the function of suppressing cellular proliferation, and/or maintaining cellular differentiation, facilitating normal cellular adhesion mechanisms, stopping entry into the cell cycle (G1, S-phase, mitosis or G2) to allow DNA-repair mechanisms, maintaining normal cellular shape, cell contact inhibition mechanisms, and so on.

Tumor suppressor genes are either underexpressed in cancer cells, because of genetic deletions or promoter hypermethylation, or have undergone other forms of loss of function genetic or epigenetic changes. For example, abnormal *p53* function can be the result of the acquisition of

point mutations, posttranslation inactivation through binding to other regulatory proteins (such as the so-called *MDM2)*, enhanced degradation (e.g. by the activity of the E6 protein of carcinogenic human papilloma viruses), or other mechanisms like decreased translation of wild-type *p53* by the folate-dependent enzyme thymidylate synthase. In these cases, depending on the cellular context and microenvironment, cancer cells are unable to undergo cell cycle arrest and/or apoptosis in response to the DNA damage produced by cytotoxic chemotherapy or radiotherapy.

Reversion of the malignant phenotype was demonstrated, over three decades ago, by the classical ''cell fusion'' experiments by Henry Harris, at Oxford. The loss of particular chromosomes in hybrid normal-malignant cells, or the gain of normal chromosomes when fusing normal cells with particular types of malignant cells *in vitro*, led to the first experimental data to back the hypothesis of ''antioncogenes,'' or tumor suppressor genes. Later experiments in the 1980s and 1990s, with the help of gene transfer methods including modified retroviruses and adenovirus, have given more support to the idea that in many cases the malignant phenotype of cancer cells can be reversed, *in vitro* and *in vivo*, by replacing a key tumor suppressor gene. However, because of the technical difficulties and the potential dangers of gene therapy in patients, these findings have not yet led to clinically relevant forms of gene therapy.

An alternative approach, based on the binary state of most regulatory molecules, as proposed in ''Principles of Molecular Oncology'' (2004), is to develop drugs that can lock *in vitro* and '*in vivo*' a particular tumor suppressor protein into its active ''tumor suppressor function'' (Fig. 3).

The tumor suppressor paradigm characteristically calls for loss of both functional copies of the gene and indeed many, though not all, tumor suppressor genes must undergo biallelic inactivation in order to sustain a true loss-of-function effect.

An example is the PTEN tumor suppressor pathway.

In 1997, PTEN (phosphatase and tensin homolog deleted on chromosome10), was cloned and mapped to cytoband 10q23, a region of chromosome 10 that undergoes frequent somatic deletion in some malignant human tumors, in particular, in endometrial cancers (almost 50%), some brain tumors (e.g. 30–40% of glioblastoma multiforme, and to a lesser extent anaplastic astrocytomas), metastatic prostate cancers (20–60%) and malignant melanomas.

Discordance between the rate of ''loss of heterozygosity'' (LOH) and the rate of mutation of the second allele of the *PTEN* gene, has led some to suggest that a second tumor suppressor gene is located in the 10q23 region, but this difference could also due to other reasons: (1) technical inability to detect second mutational events (low sensitivity); (2) a gene dosage-effect where loss of one allele of *PTEN* may have a partial tumor promoting effect; c) epigenetic alterations in the *PTEN* gene, the mRNA, or corresponding protein; d) cooperation between loss of only one allele of *PTEN* and a genetic event in another not-yet-identified gene. The PTEN protein is also regulated by phosphorylation. In particular the serine/threonine kinase CK2, upregulated in many cancers, phosphorylates the PTEN C-terminal tail and reduces PTEN activity, raising the possibility that phosphorylation of PTEN by CK2 might be a mechanism contributing to the downregulation of PTEN in certain human cancers retaining a wild-type PTEN allele. In consequence, inhibitors of CK2

might prove useful therapeutic agents in some cancers.

Whatever be the reasons, loss of PTEN tumor suppressor protein leads to constitutive activation of the PIP3 (phosphatidylinositol-3,4,5-trisphosphate) pathway, with important downstream consequences, *via* the molecular participation of Oncogenic Protein Pathways (like Akt pathways and the m-TOR protein that derives its name from ''mammalian target of rapamycin''). This process results in significant changes in cell cycle progression, survival, cell spreading and motility, and even in the angiogenic properties of tumor cells.

This PTEN/PI3K molecular system provides an example of an elegant ''on-off switch'' that has been evolved as ''nutrient and growth factor response pathways''where the switch moves to ''on'' position when PI3 kinase (PI3K) deposits a phosphate group on the D3 position of the inositol ring, while it is turned ''off'' when the PTEN removes the phosphate group from the same position.

Another important example of a TS that can prove to be a valid target for cancer therapy is *p53*. Underactivity of *p53*, caused by loss-of-function mutations, encourages the growth of cancer, whereas its overactivity can accelerate the aging process and cell death. Following some elegant pioneering work by Snyder and colleagues (recently reviewed by David Lane in the New England Journal of Medicine), a synthetic 34-amino-acid peptide, made of *d*-amino acids, rather than the conventional *l*-amino acids, and called *RI-TATp53C*, has been shown to be a potent activator of DNA-binding and tumor suppressor functions in both wildtype and mutant *p53*. In preclinical models, this synthetic peptide, that cannot be degraded by proteases and is internalized into cancer cells by a lipid-raft-dependent pinocytosis mechanism, has been shown to achieve complete cures in a mouse model of terminal peritoneal lymphoma.

New cancer therapies will be directed not merely to hit the DNA synthetic machinery, but to hit selective targets at or downstream from abnormally activated catalytic functions (thereby abrogating the abnormal stimulatory signals), or at or upstream from inactivated or missing catalytic functions (switching on parallel or alternative regulatory pathways).

Multitargeting The ''oncogene addiction hypothesis'', first put forward by Weinstein, emphasizes the importance of oncogenes or tumor suppressor genes in the maintenance and initial development of any given cancer. In other words, some cancers are extremely dependent on only one or a few oncogenic changes, and may be inhibited by one or a few target-oriented drugs. The correction of a key oncogenetic lesion in a cancer that has undergone a multitude of other activating oncogenic events may nevertheless provide anticancer effects. Although the main clinical examples of such 'Achilles heels' of cancers are provided by relatively unusual tumors like chronic myeloid leukemia, and c-KIT mutants like GIST-tumor (both very sensitive to the therapeutic effects of Imatinib), the situation in most common solid tumors is probably more complex. For example, even in breast cancers that express, by IHC, huge numbers of HER-2 targets (tumors considered to be candidates for Herceptin must express positivity of HER-2 in over 80% of cells, or positivity for FISH with a chromosome amplified ratio of 17 or more), the use of Trastuzumab may lead to response rates of only around 30% when used alone,

and 50% when combined with conventional cytotoxic chemotherapy. The use of new HSP90 inhibitors can tackle several carcinogenic targets at once, the so-called *hallmark traits of cancer*, because HSP90 is a molecular chaperone that stabilizes several mutated and overexpressed ''client'' signaling molecules such as many oncogenic kinases or even the catalytic component of telomerase. Inhibition of HSP90 leads to incorrect folding and subsequent degradation of oncogenic client proteins through the ubiquitin-proteasome pathways, but this ''promiscuity'' of action of HSP90 inhibitors can also lead to less specificity, lower anticancer potency and more potential iatrogenic side effects.

Other multitarget agents currently undergoing clinical development include: (1) SU11248, an oral multitargeted kinase inhibitor with direct antitumor as well as antiangiogenic activity, *via* the targeting of the VEGF, platelet-derived growth factor, KIT, and FLT3 receptor tyrosine kinases; (2) PTK87/ZK 222584, an potent orally administered inhibitor of the VEGF-mediated Flt-1 and Kinase Domain-containing Receptor(KDR) family of tyrosine kinases; (3) BAY 43–9006, again an orally given drug that inhibits Raf-1, but also other membrane receptors and molecular targets; (4) CCI-779, a novel mammalian target of rapamycin (m-TOR) kinase inhibitor, that may be useful in tumors with *PTEN* mutations, or alterations in the Akt activity pathways, regulated by PI3-kinase and *PTEN* suppressor genes.

One obvious regulatory pathway with direct relevance to cancer therapeutics is Cell Cycle Control.

From an almost 'military' point of view, the 'heart of the matter' of tumor cell growth and survival is more likely to be in the nucleus of cancer cells (downstream), than on the cell membranes (upstream).

The role of cyclin D1 in circumventing the cell-cycle checkpoints has been known to be crucial for the pathogenesis of some nonHodgkins Lymphomas and also in colon cancer, and its relationship with intracellular catenin levels have recently come to light. In most cancers, a defect in the retinoblastoma checkpoint is what allows cells to divide uncontrollably and excessively. But usually, in colon cancer, this checkpoint is surprisingly free of defect, and for a long time it was unclear how colon cancer cells achieved a proliferative advantage over their normal counterparts. Then several researchers started to link the intracellular catenin levels with the tumor suppressor protein known as *adenomatous polyposis coli* (*APC*).

The search was on for the target of *beta*-catenin. Osamu Tetsu and Frank McCormick at the University of California in San Francisco published a key paper in 1999, linking intracellular catenin directly with increased expression of cyclin D1, thereby prompting cells to enter the S-phase.

High levels of cyclin D1 override the checkpoint in colonic epithelial cells, generating a population of cells that will not be totally transformed, but might acquire further mutations, for example in *Ras* or other oncogenes, to acquire the truly malignant phenotype. The two pathways, Ras and beta catenin-APC, somehow converge into the same apparent bottleneck activating the expression of cyclin D1.

Similarly, cyclin E has a pivotal role in transducing the mitogenic stimulus of several hormones, cytokines, and extracellular growth factors. Transient expression of cyclin E induces the formation and activation of CDK2 complexes and, as explained before, pRb is again a key substrate. It seems that pRb must be phosphorylated

by CDK4/cyclin D before being phosphorylated by CDK2/cyclin E.

Recent evidence suggests that levels of total cyclin E (and low-molecular-weight cyclin E) in tumor tissue, as measured by Western blot assays, correlate strongly with survival in patients with breast cancer.

In a retrospective analysis of 395 patients with breast cancer with a median follow-up of 6.4 years, high levels of truncated or total cyclin E correlate with poor disease-specific survival. Among patients with early (stage I) breast cancer, all those with low levels of cyclin E were alive at seven years, as compared with none of those with expression of high levels of cyclin E. If these findings are confirmed by others, then determination of cyclin E levels by an immunohistochemical assay might soon become routine in oncology units. Stimulation of the proliferation of breast cancer cells by estrogens and growth factors is also accompanied by increased cyclin E levels and the formation of active cyclin E–cdk2 complexes.

From the above arguments, it is obvious that selective inhibitors of cyclin E and D are good candidates for cancer therapy. Molecules designed to inhibit the binding of these cyclins to their corresponding pockets in CDKs (particularly CDK2 and CDK4) are being designed and developed, and some might soon be under preclinical development. Structural studies, for example, have focused on how RXL (cyclin-binding motif) and LXCXE (part of cyclin structure) contribute to substrate selection. The RXL motif in *p27* is thought to bind to a hydrophobic surface on cyclin A. This surface is conserved between cyclins A,B,D and E (lying opposite to the CDK2-binding site).

Cyclin-dependent Kinase Inhibitors (CKIs) can provide us with basic clues on how proliferation is normally controlled *in vivo*, on new classes of clinically relevant prognostic factors in cancer, and on how to develop molecular mimetics with high affinity for CDKs, and similarly potent inhibitory actions. Synthetic d-peptides (as opposed to naturally occurring l-peptides) are also being investigated in this context as potential allosteric pharmacological regulators of CKIs.

Molecular dynamics simulations can provide complementary information on the nature of these interactions. Owing to the large contact surface between both proteins, it is difficult to design a single small-molecular-weight drug capable of embracing all the interactions deduced from the crystal structures and the molecular dynamic simulations. However, increasing insight into the design of small molecules with sufficient selectivity to alter the T-loop conformation and distortion of the ATP binding site is gradually been achieved. Moreover, the development of short-chain synthetic peptides capable of inhibiting normal binding of p16 to CDK4 can allow a better understanding of the key structure, activity and allosteric properties of these complex molecular interactions.

Gene transfer experiments, for example transfection into tumor cells in culture of active CKI genes, has enabled several laboratories to test the principle of the induction of tumor regression by the activation, or transfer, of CKI activity A good illustration of this is that ectopic p18 expression inhibits growth and induces apoptosis of multiple myeloma (MM) cells. In about a quarter of human MM cell lines, cyclin D1 is overexpressed because the *cyclin D1* gene is brought under the influence of immunoglobulin heavy chain (IgH) enhancer and promoter elements by chromosomal translocation t(11;14)(q13;q32). The CKI p18 predominantly binds to CDK6 and, to a lesser extent, to

CDK4 and inactivates their kinase activity. Furthermore, p18 can efficiently block CDK6 phosphorylation by CAK/cyclin H1. Cell lines transfected with an inducible p18 expression vector not only exhibited growth inhibition, but also apoptosis.

Microinjection of CKI proteins has also confirmed other biological activities of CKIs. For example, injection of the CKI p21 and p27 in *Xenopus laevis* embryos blocked centrosome duplication. The centrosome nucleates the polymerization of microtubules and duplicates once per cell cycle starting at the G1-S transition, and plays a major role in organizing the poles of the mitotic spindle. The inhibition of normal centrosome function by p21 and p27 can also arrest cell growth, and lead to abnormal segregation of chromosomes.

Another unexpected property of CKI is the reported ability of p21 (WAF1/CIP1) to restore hormone responsiveness to estrogen-receptor (ER)-negative breast cancer cells. Again, the overexpression of p21 with a tetracycline-inducible gene transfer vector can make ER-negative, p21-negative breast cancer cells sensitive to growth inhibition by anti-estrogens. A strong positive association has been found between the expression of p21 and the presence of ER in tumor samples from 60 patients with breast cancer.

Besides gene therapy approaches, *in vivo* protein and peptide transduction systems are also being investigated by several laboratories. Recombinant proteins, like recombinant human colony-stimulating factors, have been used in cancer patients for some 15 years already. However, the inability of molecules larger than 600 daltons to cross the plasma membrane has restricted the pharmacological use of proteins to those which function outside the cell, for example, by binding to specific cell membrane receptors. Most tumor suppressors, on the other hand, are intracellular, and therefore cannot be administered to patients as recombinant proteins directly.

At first sight, the retinoblastoma (Rb) protein is the true bottleneck of most of these cell cycle–controlling pathways. In 1986-87 the tumor suppressor *Rb* gene, first identified because it mutated in hereditary retinoblastomas, was cloned by three different laboratories headed by eminent molecular biologists: Robert A. Weinberg and Thaddeus Dryja, William Benedict and Yuen-Kai Fung, and Wen-Hwa Lee. It is a rather large gene, over 200-kb long, and with 27 exons. It codifies for a nuclear protein of 928 amino acids, which is constitutively expressed during the cell cycle, but with characteristic cell cycle dependent varying degrees of phosphorylation.

Phosphorylation of pRb is carried out initially by D-type cyclins (in protein complexes with CDK4 or CDK6) followed later by cyclin E/CDK2. Virtually all human tumors tested so far show mutations that directly or indirectly alter the normal function of *Rb*. Nearly all tumor-derived *pRb* mutants have lost the ability to repress E2F-responsive genes, and reintroduction by gene transfer of wild-type pRb into Rb −/− tumor cells leads to restoration of E2F control and cell cycle arrest. There are at least six human *E2F* genes (*E2F*1 to *E2F*6) and their protein products bind to specific DNA sequences as heterodimers with either DP1 or DP2 proteins. It is now clear that binding to pRb converts the E2F family from transcriptional activators to potent transcriptional repressors. E2F*6*, unlike the other E2F family members, is an intrinsic transcriptional repressor and does not apparently interact with pRb family members.

Hyperphosphorylated pRb is unable to maintain the binding and inactivation of E2F, and free E2F molecules lead to transcription of multiple genes involved in the initiation of DNA synthesis and cellular proliferation.

Using gene expression profiling methods (Affymetrix GeneChips) it has been possible to demonstrate changes in the expression of over 200 genes, most of them involved in cell cycle control, by CDK phosphorylation of wild-type *pRb*. Some of these genes are also involved with DNA repair, or changes in chromatin structure. As expected, a significant fraction of Rb-repressed genes have promoters that are bound/regulated by E2F family members. However, targets were also identified that are distinct from genes known to be stimulated by overexpression of specific E2F proteins, suggesting that some of the multiple pRb effects are not directly related to E2F proteins.

The conformation and activity of pRb is rather complex, and not fully understood. It is widely accepted that the activity of this large tumor suppressor protein is largely dependent upon the phosphorylation status of at least 16 potential CDK phosphorylation sites. But how exactly the phosphorylation of any of these sites changes the full range of activities of pRb remains a matter of intense study. Low-molecular-weight drugs designed to block 'site-specific phosphorylation' of these sites are also under study, as they may ultimately arrest the growth of populations of tumor cells.

Yuen-Kai Fung's laboratory at the University of Southern California has identified all the CDK sites (Thr-356, Ser-807/Ser-811, and Thr-821), the phosphorylation of which drastically modifies the conformation of pRb. The so-called *m89 structural motif* (identified in the m89 mutant of pRb) has greatly enhanced growth suppressing activity, similar to a mutant with alanine substitutions at Ser-807/Ser-811. Moreover, this m89 region is part of a structural domain, p5, conserved antigenically and functionally between pRb and p53.

Rationally designed drugs capable of interacting with these key molecular sites may exploit the coordinated regulation of activity of these two tumor suppressors, or at least block the conformation of the tumor suppressor pRb into its active growth inhibitory hypophosphorylated structure (see also Fig. 3).

One of the seemingly tragic, and yet-unexplained, features of our human genome is that the key sensors that control many of the functional interactions between Rb and p53 are actually linked in the same gene, making them dually vulnerable to the same genetic attack. In general, mutational events that disable the Rb pathway and facilitate cell proliferation are counterbalanced by a p53-dependent response that eliminates, or at least inhibits, incipient cancer cells. Conversely, loss of p53 function enables cells that sustain oncogenic damage to survive and proliferate. Unfortunately for us, as explained before, the INK4A-ARF locus encodes, in the same genetic locus, two distinct tumor suppressor proteins that regulate both the Rb and the p53 pathways. ARF (p19) is a sensor of inappropriate proliferation brought about by loss of Rb. The product of the *p53* gene is part of the intrinsic mechanisms that monitor the cell cycle. For example, inducing the expression of p21, and mutations, deletions or underexpression of p19ARF facilitate MDM2's degradation of p53, leaving the cell unaware of the need to initiate cell death.

To complete the picture, reactivation of telomerase activity, normally suppressed in most normal human tissues, can dramatically contribute to the carcinogenesis process. Telomerase activity is needed to maintain chromosomal stability, particularly at the – tips of chromosomes where bits of DNA are otherwise lost during each round of DNA replication and cell division, because of the way DNA polymerase works and the need for ''primers.'' If it were not for the activity of telomerase, many cancer types would eventually self destroy, because of the cumulative loss of DNA material at each round of cell division.

Keywords

Bacteriorhodopsin
A naturally occurring trans-membrane protein found in the cellular membrane of *H. Salinarum*. Activated by the absorption of a photon, the protein undergoes a photocycle, with a number of spectroscopic active intermediates, as it pumps protons across the cell membrane to form chemical energy from sunlight.

Biomolecular Devices
A system that carries out a function that uses a biological molecule to carry out all or a portion of the device function. If the device is electronic or photonic, the term bioelectronic is often used, and if semiconductor technology is involved, the adjective hybrid is added.

Biophotonics
A device that uses or manipulates light to carry out function and uses a biological molecule as the active component in the reception or manipulation of the light.

Directed Evolution
The iterative process by which genetic modification and differential selection are used to optimize any genetically amenable parameter of a biological molecule.

Mutagenesis
A group of molecular biology techniques that can produce changes in the DNA sequence of a gene and in the structure or function of a protein for which it codes.

Protein Optimization
The process of altering the primary, secondary, or tertiary structure of a protein to enhance its function in a device application. Protein optimization can be carried out by using chemical or mutagenic methods, and if a chromophore is involved, *via* substitution of the native chromophore with a modified version.

Thermostability
The temperature at which a protein becomes irreversibly inactivated. Stabilizing interactions may be introduced into a protein *via* genetic modification to increase its temperature threshold.

Protein-based bioelectronic devices have emerged as practical alternatives to semiconductor-based technology. While nature does not optimize biological molecules for performance in device applications, present-day genetic engineering has enabled investigators to manipulate the speed, durability, and architecture of candidate molecules. The biophysical, chemical, electronic, and thermal parameters of certain genetically amenable molecules have been optimized *via* a technique known as *directed evolution*. Combining genetic modification with differential selection makes it possible to tailor biological macromolecules with a high degree of accuracy and speed. Genetically modified forms of bacteriorhodopsin have improved the performance of the protein in three-dimensional volumetric memories, real-time holographic media, protein-based semiconductor devices, and artificial retinas.

1 Introduction

Biomolecular electronics is broadly defined as the manipulation and study of biological molecules for use in photonic or electronic devices. Evolutionary pressure has created some biological molecules with many of the key properties necessary for device applications or to serve as templates for further optimization. A majority of the best candidates are proteins that transport ions, conduct current, transduce light or self-assemble while maintaining function. Genetic engineering provides a route to further optimization through specific or random changes to any amino acid in the protein. Biological molecules have shown comparative advantages in a number of architectures aimed at volumetric data storage, holographic memories and devices, photovoltaic receivers and converters, biosensors, and artificial retinas.

1.1 Bacteriorhodopsin as a Bioelectronic Material

Bacteriorhodopsin (BR) is a naturally occurring protein that has been optimized via natural selection to be a highly efficient light transducing protein with good thermal stability both *in vitro* and *in vivo* environments. Because this protein must function in the outer membrane of a salt-marsh archae, the protein is stable over a wide range of temperature and pH values that are encountered in extreme environments. Further advantage is derived from the fact that BR can be isolated from the native organism and produced easily and in large quantities. Because BR has been the subject of extensive device study for the past two decades, this review will focus on this protein. But the methods of optimizing this protein for device applications are applicable to any promising protein, and this chapter will conclude with a discussion of some other candidate proteins that are currently under study.

1.2 Photocycle Overview and Characteristics

Bacteriorhodopsin functions as a proton pump in the native organism, *Halobacterium salinarum*. The protein exists as a trimer in the native organism and together with membrane lipids forms

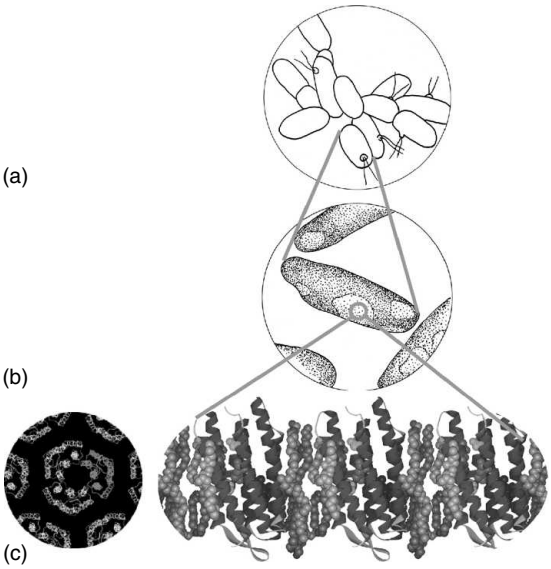

Fig. 1 Structure of bacteriorhodopsin (BR) in the purple membrane of Halobacterium salinarum. The membrane contains BR as the primary constituent, where the protein exists as a trimer in a hexagonal lattice.

a two-dimensional lattice known as the ''purple membrane.'' Figure 1 shows the structure of the lattice and protein as it occurs in the native organism. The purple color of BR is a result of the absorbance of an embedded chromophore; in solution, retinal absorbs maximally at 380 nm, but, in the native protein environment, the complex absorbs maximally at 568 nm. The trimer lattice imparts a considerable amount of stability to BR and also provides an opportunity for the protein to self-assemble into layers. Although a native lipid matrix is not required for orientation (i.e. other proteins can also meet this goal without the existence of such a matrix), it makes the task easier.

The protein is composed of 248 amino acids that form seven membrane-spanning alpha helices. Embedded in the middle of this seven helical bundle is a light-absorbing moiety called retinal. Retinal is attached to the protein via a Schiff base linkage to lysine-216. Following absorption of a photon of light, retinal undergoes a conformational change from all-trans to 13-cis. This initial light-induced isomerization induces a series of electronic and conformational thermal transitions in the protein that proceed in the absence of light. Figure 2 shows the photocycle of BR. The main photocycle intermediates are labeled bR (the initial resting state of the protein), K, L, M, N, and O (note to reader: ''BR'' is used as an abbreviation to represent the protein, whereas ''bR'' is used to represent the resting state of the light-adapted form of this protein).

There is also a branched photocycle in BR, comprised of the P and Q states. The P state can be reached by illuminating the O state with red light ($\lambda_{max} = 640$ nm). The P state thermally decays to the Q state, which is stable for long periods of time. The Q state can then be illuminated with ultraviolet/blue light ($\lambda_{max} = 380$ nm) and the protein returns to the resting state, bR. These branched photocycle intermediates are stable for long periods of time (i.e. decades) and the protein will remain in the branched state indefinitely (P or Q) until illuminated with ultraviolet/blue

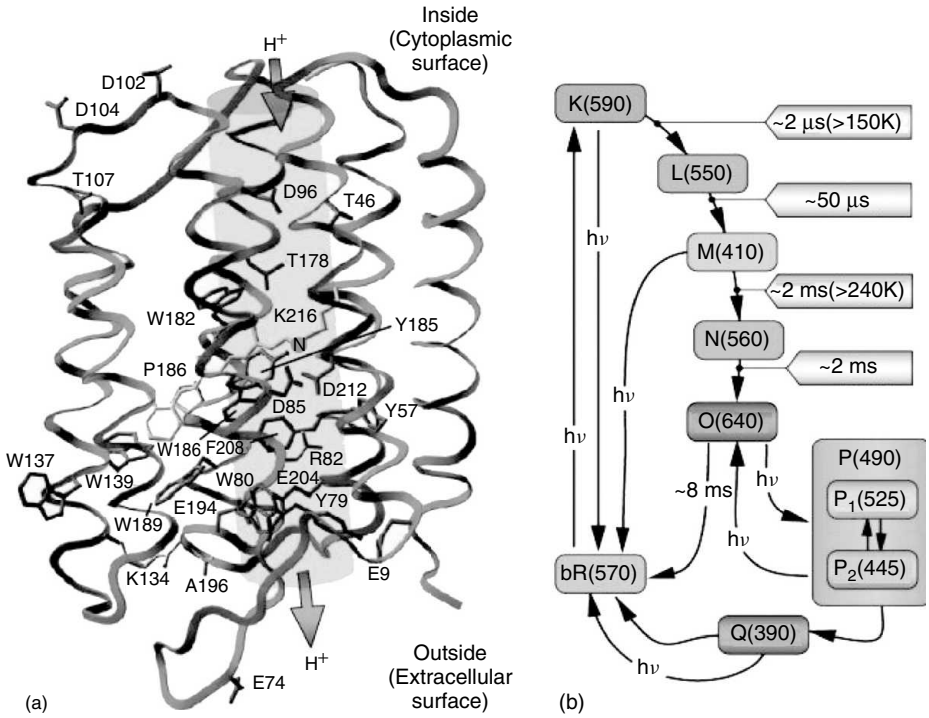

Fig. 2 Structure and photocycle of bacteriorhodopsin. Key amino acids are shown in the first panel. The second panel shows the main photocycle intermediates (bR, K, L, M, N, and O) as well as the branched photocycle intermediates (P_1, P_2, and Q).

light. The existence of this bistable system has provided promise for using BR as a template in photonic memory devices.

2 Optimization Methods for Proteins

Optimization of proteins for biomolecular electronic devices required the concerted effort of many molecular and chemical strategies. Before the insurgence of molecular techniques, traditional optimization of proteins included submitting the protein to various chemical and physical perturbations, including addition of chemicals, different solvents, and pH alteration. However, recent molecular tools have allowed for high-throughput examination of vast numbers of protein variants. Photoactive proteins can now be modified at the level of the protein, the chromophore, and the solvent environment. A unification of tools from all levels is employed to find suitable protein candidates for biomolecular electronic devices. Cross-method optimization provides the largest possibility of producing and detecting commercially viable protein variants.

2.1 Optimization Tools

A number of tools are now being used to generate photoactive protein mutants for various device applications. Mutagenesis

at various degrees of specificity is used to generate proteins that have been modified at the amino acid level. Proteins can be modified at any single amino acid or group of amino acids by mutagenesis tailored to suit the desired range of variability. The entire length of the protein can be modified randomly with no *a priori* knowledge of structure and function. Each technique can be selected depending on the desired level or specificity of variation desired. For example, a global genetic search of the entire protein may reveal a variant that can then be further studied using other optimization methods.

2.2 Genetic Modification

Table 1 summarizes the different levels of variability generation and optimization used on a protein. Mutagenesis techniques are used to generate all initial variability. Site-directed, semirandom, and random mutagenesis are used to generate genetic substitutions to one location, one region, or one gene, respectively. Directed evolution is used to iteratively generate and screen mutants that confer desired optimizations. Directed evolution type I and type II represent different levels of screening; type I involves screening on small volumes of isolated protein and type II involves screening on the actual organism expressing the protein. Table 1 shows the requirements and usefulness of each technique.

2.2.1 Site-directed Mutagenesis

Site-directed mutagenesis provides the ability to alter one specific amino acid at a time. This technique can also be used to mutate 3 to 5 contiguous amino acids. Mutation of a protein in site-directed fashion can be accomplished easily and quickly in the laboratory using any number of commercially available kits (e.g. QuikChange™ by Stratagene). Figure 3 shows the procedures and specificity provided by various mutagenesis strategies, and site-directed mutagenesis is shown in Fig. 3A. The entire process from designing mutant DNA to isolation of protein takes approximately six weeks, and most of this time (3–4 weeks) is spent cultivating *H. salinarum*, which grows at a much slower rate than commonly used *E. coli* laboratory strains.

This mutagenesis procedure can work for creating site-directed mutants in any protein given a suitable expression system (i.e. a plasmid containing the gene of interest and a method for expressing the protein) is in place. Using site-directed mutagenesis, over 100 mutants in BR have been constructed, many of which provide device optimization over wild-type (or naturally occurring) protein. Some of these mutants will be discussed later in this review. Site-directed mutagenesis is a commonly used tool in most molecular systems, and thus not limited to BR alone.

2.2.2 Semirandom and Random Mutagenesis

Site-directed mutagenesis is very useful when knowledge of the structure and function of the protein is known. However, this information is not always known. Without detailed crystal structures or higher-level theoretical calculations, it is hard to predict which amino changes will have a desired effect on the function of a protein. For this reason, more advanced mutational strategies have become popular. Semirandom and random mutagenesis are two methods to examine more global regions of a protein. An overview of these procedures is shown in Fig. 3. Semirandom mutagenesis (also called saturation mutagenesis)

Tab. 1 Generation of variability and optimization in proteins. Different mutagenesis techniques can be used to create any level of desired variability in the DNA sequence of photosensitive proteins. The specificity, variability generated, primary use, and requirements of each level is shown.

Technique	***Variability***					***Optimization Chemical, photophysical, thermal, electronic***
	Site-directed mutagenesis	***Semirandom mutagenesis***	***Random mutagenesis***	***Directed evolution 1***	***Directed evolution 2***	
Specificity	Single amino acid	Local region of amino acids	Global *bop* gene	Individual colony or protein	Individual *H. salinarum* cell	Protein or membrane patch
Variability Generated	Low	Medium	High	N/A	N/A	High
Primary use	Fine-tuning	Narrowing in on optimal mutation	New search	Colony/protein screening	Organism screening/selection	Material optimization
Requires	Modeling, *a priori* knowledge	Manageable segments	No *a prior* knowledge	Medium-throughput screening	High-throughput screening	High-level characterization

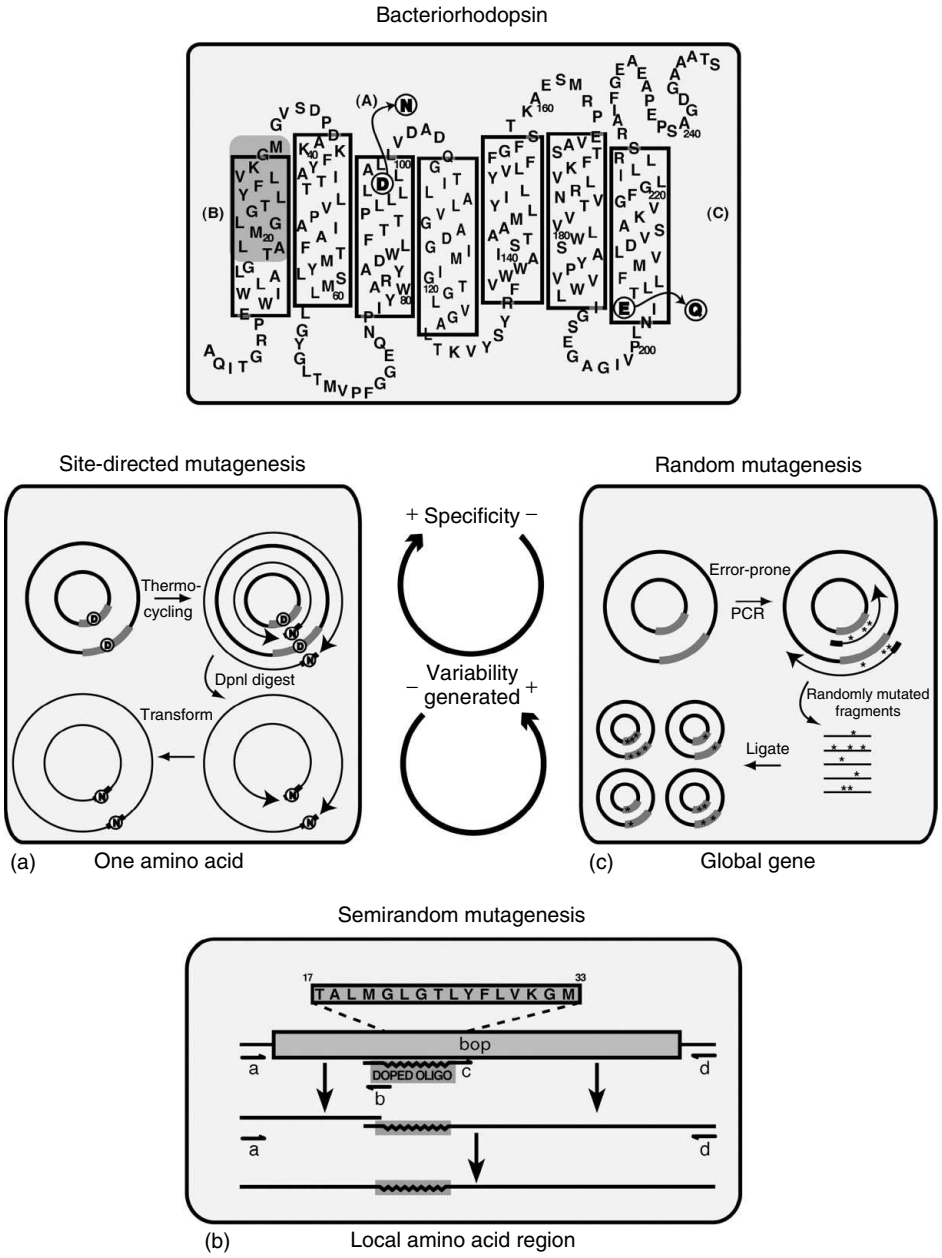

Fig. 3 Summary of mutagenesis techniques. Different mutagenesis techniques are selected based on the variability created and specificity of each technique. (a) Site-directed mutagenesis is used to modify one amino acid. (b) Semirandom mutagenesis is used to modify 10 to 20 amino acids. (c) Random mutagenesis is used to modify the entire length of the protein coding sequence.

involves mutation of a local region of 10 to 20 amino acids, while the remainder of the protein remains unaltered. For random mutagenesis, the entire protein region is affected; all amino acids are mutated with equal probability across the entire length of the protein.

Semirandom mutagenesis involves partitioning of the protein into short segments that are mutated independently. This approach was originally established by Sauer and co-workers and was also used to examine membrane protein folding and function. For example, BR contains 248 amino acids that were divided into 15 segments of ~15 amino acids each. Each segment contains a certain percentage of ''doping'' or probability that one amino acid is replaced by another amino acid. For example, a doping level of 20% means that there is an 80% chance that the wild-type nucleotide remains and a 6.7% chance this nucleotide is mutated to any other. Photophysical optimization of BR was accomplished using semirandom mutagenesis, and these results will be presented in Sect. 2.5.

Random mutagenesis is accomplished using many different molecular techniques, including error-prone PCR and the use of cell lines designed to introduce mutations due to errors in DNA replication mechanisms. With random mutagenesis, the entire gene is mutated with no *a priori* bias in sequence. The advantage of this technique is that no knowledge of protein structure and function is required.

The various mutagenesis techniques are most efficient when used concurrently. As shown in Fig. 3, an increase in specificity is achieved by moving from random to semirandom to site-specific mutagenesis. An increase in the amount of variability created is achieved by using the opposite order; the most variability can be created across the entire gene sequence by using random mutagenesis. For example, semirandom and random mutagenesis can be used to locate a region conferring an optimization. Then, site-directed mutagenesis can be used to dissect the particular residues responsible for a given optimization and examine their respective contributions to the overall effect.

2.2.3 Directed Evolution and Organism Selection

Directed evolution at the molecular level is the process whereby multiple iterations of mutation and selection result in proteins with optimized characteristics. Directed evolution can be used to optimize any protein, provided that an efficient method for generation and screening of mutants is in place and that the optimization is fundamentally possible (i.e. the character is able to optimized). Once these criteria are met, many different aspects of a protein can be optimized for use in biomolecular electronics devices. Many enzymes have already been optimized via directed evolution.

A typical round of optimization entails construction of new mutants, either by using semirandom or random mutagenesis, screening or selection of optimized variants, and identification of these variants. Mutants are then refined and tested using site-directed mutagenesis, and the process is repeated. Multiple rounds of this process result in directed evolution of an optimized characteristic. Typically 4 to 6 rounds of directed evolution produce significant optimizations, although it is possible to find a desired optimization in less.

Organisms that afford the ability to screen variants *in vivo* can be optimized more efficiently by elimination of time-consuming (and often expensive) protein isolation procedures. The efficiency of

the chosen screening method is the critical rate-limiting step in directed evolution procedures. However difficult *in vivo* screening and selection methods may be to devise, development of a successful method provides the ultimate streamlined tool in protein optimization. The ability to generate and screen proteins in the native organism avoids many *in vitro* steps and allows for a more high-throughput screen. The greatest chance of detecting an optimized protein is directly related to the number of proteins able to be screened in the shortest amount of time. For BR, rounds of semirandom mutagenesis have been coupled with site-directed mutagenesis to generate novel protein constructs. The protein has been optimized photophysically, and thermal optimization experiments are currently being conducted.

2.3 Optimization Goals for Biomolecular Electronic Devices

Despite the remarkable efficiency of proteins in the natural world, laboratory and device usefulness of proteins remain suboptimal. While nature has optimized proteins for speed, accuracy, and efficiency, these same attributes result in proteins that require significant modification if they are ever to be realized for device application materials.

There are many optimization goals for a particular protein for use in bioelectronic devices. Figure 4 shows the different ways that a protein such as BR is being used as a biomolecular photonic device. Four classes of optimization are chemical, photophysical, thermal, and electronic. Chemical modification involves the addition of additives and modification of the light-absorbing moieties in photosensitive proteins. Photophysical modification of proteins involves tailoring of the photocycle to meet specific photonic requirements. Thermal optimization involves increasing the denaturation temperature of proteins for increased stability in devices. Electronic optimization involves adjusting charge motion or net charge to enhance the photovoltaic properties and orientation capacity of the molecule for device applications.

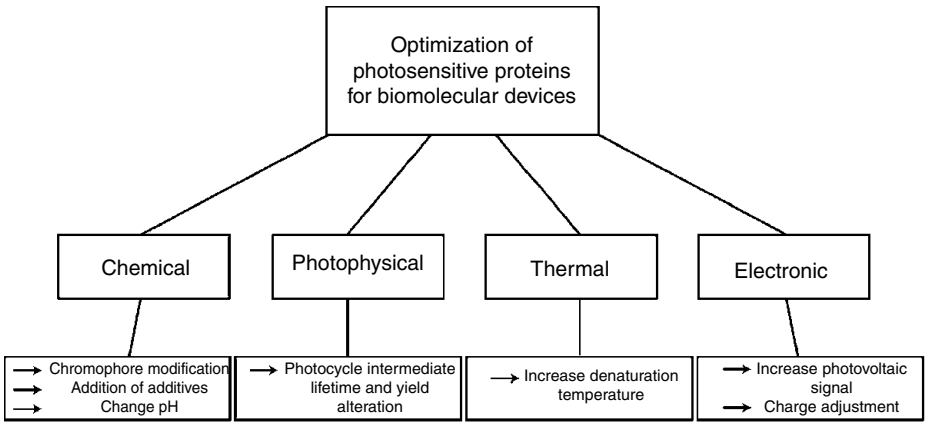

Fig. 4 An overview of the types of optimization targeted for use of a protein in biomolecular devices. The different types of optimization include chemical, photophysical, thermal, and electronic.

2.4 Chemical Optimization of Proteins

Some of the easiest changes to proteins in terms of cost and time requirements can be accomplished by changing the physical environment of the protein. Variations in pH, solvent, temperature, ionic strength, and addition of inorganic and organic chemicals can all result in altered protein structure and function. Chemical modification of any apoprotein moieties that may exist in the molecule can be used to alter the structure and function of those constituents.

2.4.1 Chemical Additives in Bacteriorhodopsin

The photocycle of BR can also be adjusted by the addition of chemical additives. Lowering the pH to less than 2.5 results in a color change from purple ($\lambda_{max} =$ 568 nm) to blue ($\lambda_{max} = 605–610$ nm). This ''blue membrane'' results in abolishment of the photocycle. Other additives also have an impact on the photocycle of BR. Glycerol has been shown to inhibit the P $\rightarrow$ Q transition; because P $\rightarrow$ Q is a hydrolysis reaction, removal of water and addition of glycerol results in inhibition of Q state formation. Glycerol also results in longer lifetimes to main photocycle intermediate kinetics. These results have been important in understanding how BR functions in three-dimensional memories and in further elucidation of the P state.

BR has a number of naturally occurring cations present in the protein, consisting of monovalents and divalents such as calcium, magnesium, and sodium. Removal of these cations results in a shift from purple membrane to blue membrane. Replacement of these naturally occurring cations with synthesized cations known as ''bolaforms'' can restore the purple color of BR and also result in altered photokinetics. It is uncertain how these organic cations exert their effect on the photocycle of the protein, or where they bind in the protein, but this does not preclude their usefulness in biomolecular devices.

2.4.2 Chromophore Analogs in Bacteriorhodopsin

The retinal moiety of BR has been modified using standing organic chemistry techniques. A sample of two chromophore modifications to the retinal molecule in BR is shown in Fig. 5. Modification to the retinal molecule often results in altered photophysical kinetics. The BR variants 13-desmethyl BR and 4-keto BR were synthesized by removal of the C13 methyl group and by addition of a ketone group at C4, respectively. Studies were conducted to examine the relative conformations of the chromophores when inserted back into the protein. Whereas wild-type protein consists of a mixture of all-trans to 13-cis isomers of 50 : 50 in the dark, and 98 : 2 in the light, 13-desmethyl BR consists of a mixture of 15 : 85 in light or dark (i.e. 13-desmethyl BR does not ''dark adapt'' or ''light adapt,'' or shift the relative proportions of retinal isomers when illuminated, as does wild-type protein). The other analog, 4-keto BR, results in a resting state absorption maximum of 510 nm. The M state in 4-keto BR has a vibronic structure in the M state not seen in wild type or 13-desmethyl BR. The photocycles of 13-desmethyl BR and 4-keto BR are therefore very different from the photocycle of wild-type BR and show that chromophore analogs can be used to alter the photochemistry of biomolecular BR-based systems. These results support the usefulness of modification to the apoprotein constituents of proteins

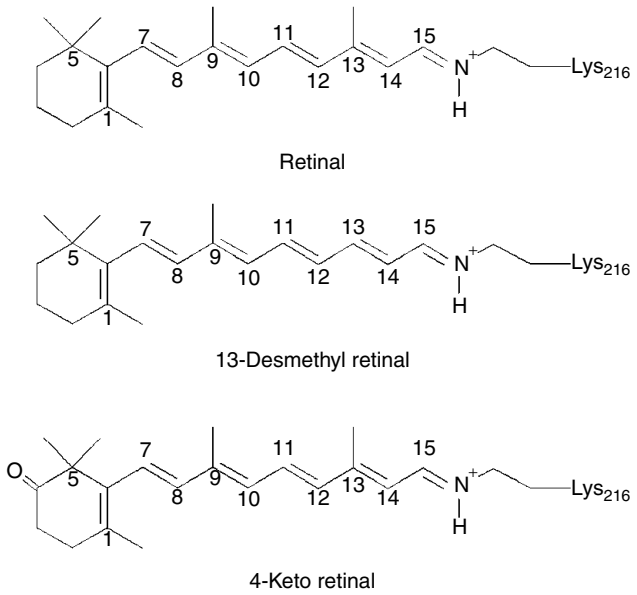

Fig. 5 Retinal isomers. Modification of the retinal molecule can be used to optimize BR for biomolecular device applications.

in addition to adjusting the amino acid structure to achieve desired photokinetic changes.

2.5 Photophysical Optimization of Proteins

Many proteins that absorb light undergo conformational and electronic changes. However, proteins with high cyclicity "reset" efficiently and, thus, following any initial changes induced by the absorbance of light, the protein is required to return to the original state. Mutations to any amino acid that has an effect on this normal functioning of the protein will adjust one or more photocycle intermediates as the protein attempts to return to the resting state.

Two bioelectronic devices have already been constructed based on the photocycle properties of BR, but many other devices are being designed. Two of these photonic devices, holographic memories and three-dimensional based memories, have been constructed using molecular variants of the protein that impact the M state and the O state (see Fig. 2).

2.5.1 Holographic Memories: The M State in Bacteriorhodopsin

The M state in BR is the most blue-shifted of all the photocycle intermediates. Holographic memory devices based on the M state take advantage of the fact that the refractive index of the M state is far removed from that of the bR resting state. A commercially available device, called the Fringemaker®, has been constructed based on a mutant variant that lengthens the M state. This mutant has a lengthened M state as a result of replacement of one aspartic acid residue to an asparagine residue at position 96 (also known as D96N). In naturally occurring protein, the lifetime of the M state is ~15 ms, but,

in this mutant variant, the lifetime of the M state reaches ~250 ms under standard conditions and pH 7. This mutant was constructed using site-directed mutagenesis. A number of long M state mutants have also been found using semirandom mutagenesis techniques, and these mutants are currently being investigated (data not shown).

2.5.2 Three-dimensional Memories: the O State in Bacteriorhodopsin

Because two distinct photocycles exist in BR (one composed of the bR, K, L, M, N, and O intermediates, and the other composed of the P and Q intermediates), information can be stored in the protein and controlled photonically (see Fig. 2). A three-dimensional memory storage device has been constructed based on the photocycle properties in BR. Significant advances to the protein for use in three-dimensional memory storage have come from site-directed and semirandom mutants. Protein mutants have been found that significantly increase the lifetime and yield of the O state. The lifetime of the O state has been increased to greater than 1 s (as compared to 20 ms in wild-type protein) using a combination of site-directed and semirandom mutagenesis techniques. Although this long lifetime is not optimal for use of BR in three-dimensional memory systems, the information provided by long O state mutants has provided valuable information about the nature of the O state and of the O to P transition.

2.6 Thermal Optimization of Proteins

Recent advancements in the field of biomolecular electronics have led to the development of device applications that utilize proteins, DNA, and a wide variety of synthetic macromolecules. While many of these macromolecules are stable in their native environments, most do not possess the degree of thermostability required for use in biomolecular electronic devices. Most organic macromolecules do not inherently possess the structural integrity to function at high temperatures, although a limited number of macromolecules thrive in extremely thermophilic environments.

Proteins with low to moderate thermostability can be engineered to function at extreme temperatures by amino acid sequence modification and computational modeling. Modeling and sequence comparisons can be used to visualize and predict regions of a protein that have poor structural integrity at high temperatures. By aligning the sequence of a thermostable protein to an analogous, mesophilic counterpart, the identity of residues likely to confer increased thermostability of the protein can be identified. Residue substitutions are then engineered into the protein to improve thermostability using the mutagenesis techniques discussed earlier.

A typical round of thermoselection is shown in Fig. 6. Pools of mutant proteins are screened for functional and structural integrity at high temperatures. Mutants that remain stable at the desired screening temperature are tested in device applications and subject to additional rounds of directed evolution for further optimization.

2.6.1 Increasing the Thermostability of BR using *Thermus thermophilus* as a host

In order to conduct directed evolution and optimization of proteins at higher temperatures, a suitable host organism must be chosen for expression of mutant proteins. For increasing the thermostability of BR, *Thermus thermophilus* (*T. thermophilus*) was chosen. *Thermus*

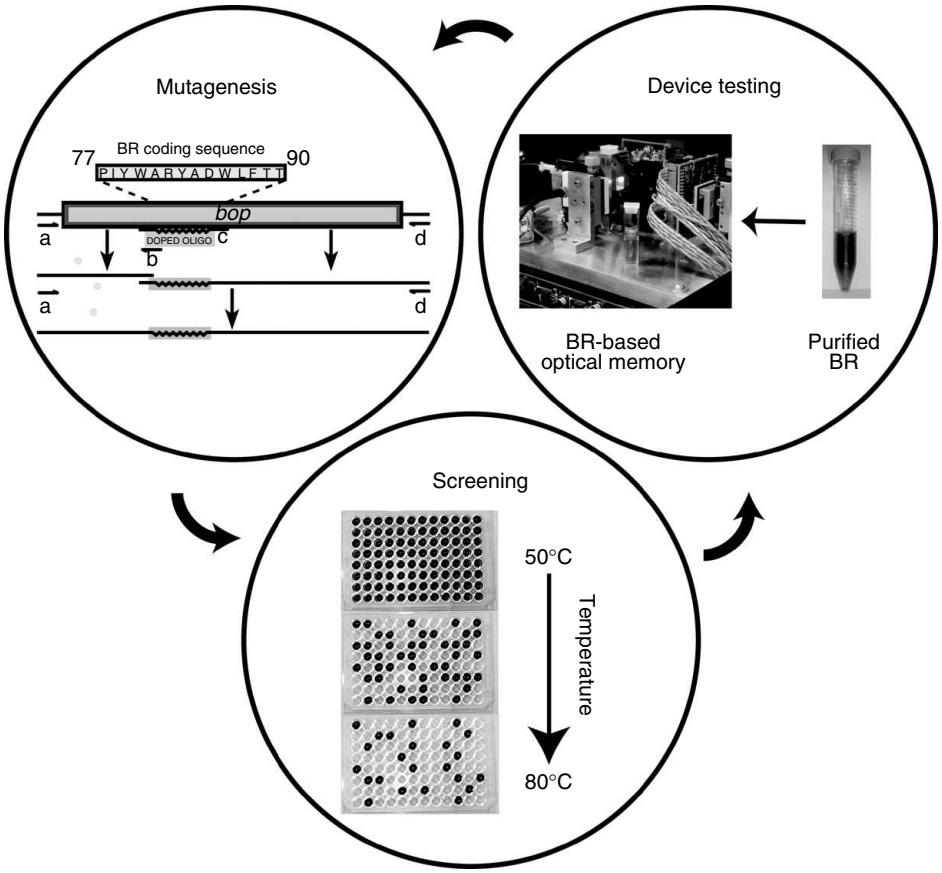

Fig. 6 A summary of a round of thermal optimization. Proteins are iteratively subjected to rounds of mutation, screening, and device testing.

thermophilus is an extremely thermophilic bacterium that grows in hot springs and industrial composts. This organism grows at temperatures in excess of 80 °C and is highly proficient at incorporating foreign DNA into the genome. These features have made *T. thermophilus* an attractive candidate to host directed evolution studies on mesophilic proteins. Recently, genetic tools were created for expression of heterologous proteins in *T. thermophilus*. These tools include thermostable antibiotic resistance selection and high copy number expression vectors. Such tools make *T. thermophilus* an efficient system to express large numbers of foreign mutant constructs at high temperatures.

Using the thermophilic expression vector described by Moreno et al., large numbers of BR variants are currently being expressed in *T. thermophilus*. The unique purple color of BR and absorbance band at 568 nm make the protein easily detectable in whole cell cultures of *T. thermophilus*. Mutant cultures are monitored relative to wild type to detect increased thermostability. Those mutants that retain structural integrity at higher temperatures

are isolated, tested for functional stability using UV-vis laser spectroscopy, and used as starting points for further rounds of mutagenesis and selection.

Bacteriorhodopsin variants that retain functional stability at the highest thermoselection temperatures are subjected to *beta* testing in biomolecular electronics devices. The performance of thermostable mutants in device applications determines whether additional optimization rounds are required.

In comparison to the work currently being conducted on BR, directed evolution has already resulted in optimization of thermal stability in a number of important enzymatic proteins. Thermally optimized enzymes are attractive agents for industrial fermentation systems, pharmaceutical treatments, and thermostable tools for genetic engineering. While these studies are significant, optimizing the thermostability of BR provides the first account of directed evolution being used to improve a membrane protein for device applications.

2.7 Electronic Optimization of Proteins

Electronic optimization of the charges and charge motion in a protein can assist in deposition and fabrication ability of the molecule for device applications. The initial photovoltaic signal present in photosensitive proteins can be enhanced in terms of both magnitude and strength of the signal by altering amino acids near the binding site of the chromophore.

2.7.1 Oriented Bacteriorhodopsin Films and Layer-by-layer Assembly

Orienting BR in a gel matrix or on a solid conductive support is achieved by a variety of deposition techniques. These techniques include electrophoretic sedimentation, Langmuir–Blodgett deposition, and immobilization onto planar lipid membranes or gel matrices. Electrophoretic sedimentation is a deposition technique used to orient an organic material between two conductive substrates by applying an external voltage. However, exposing most organics to external voltages can be damaging to both the structure and function of the macromolecule. The Langmuir–Blodgett technique involves the transfer of liquid monolayers of organic material to a solid substrate. While this technique can control the thickness and orientation of the organic components in a film, a high degree of precision is required to transfer a single monolayer of protein from liquid to solid phase. Electrostatic layer-by-layer assembly was developed out of a need for a nondestructive deposition technique that controls the thickness and orientation of an organic macromolecule onto a solid substrate with minimal expertise.

Recently, electrostatic layer-by-layer assembly was used to fabricate oriented thin films of BR (in the form of purple membrane fragments) without applying an external voltage or using a bulky polymer matrix. Layer-by-layer deposition uses electrostatic forces to orient a bilayer of protein and a polyelectrolyte (a polycation in the case of BR) to a solid substrate. In the case of BR, the cytoplasmic side of the protein is more negatively charged than the extracellular side in alkaline conditions. The dipolar nature of BR at high pH enhances its capacity to bind to a layer of polycations.

The substrate of choice is initially treated with potassium hydroxide to give it a layer of negatively charged ions on its surface. The negatively charged substrate is then dipped into a polycation solution to line it with a uniform layer of positive

charges. Upon removing the loosely attached polycation molecules with a series of washes, the substrate is dipped into an alkaline solution of BR. The cytoplasmic side of the protein attaches to the positively charged substrate, thus resulting in a uniform bilayer of polycation and protein. The layer-by-layer dipping procedure is quick (~12 min/layer), easily performed, and amenable to a number of different substrate shapes and orientations. Automating this procedure is possible when films with 100 to 200 bilayers of protein/polycation are needed.

There is a direct relationship between the number of deposited bilayers of protein/polycation and optical density of the thin film. Alternate layer-by-layer deposition proves that it is possible to both orient and control the number of bilayers assembled onto a solid support. This strategy can be used for other proteins in addition to BR and has a profound effect on the fabrication of thin films for biomolecular device applications.

2.7.2 Photovoltaic Signal Enhancement

Many photoactive proteins generate a fast, high intensity photoelectric signal upon light excitation. The photoelectric response of BR is a multicomponent signal that is triggered by the photoisomerization of a bound retinal molecule and a series of structural rearrangements of the protein. The ultrafast onset of the photovoltaic signal makes BR an appealing candidate for biomolecular field effect transistors and optoelectronic integrated circuits. A drawback to the fast photoelectric response of BR is the relatively long decay time of the signal (~4.5 ps). Utilizing BR as an efficient photodetecting element requires that the protein generate a signal with an ultrafast onset and decay time. Optimization of the photovoltaic response of the protein is achieved by employing a combination of mutagenesis techniques to alter residues in the retinal-binding pocket. Retinal analogs are also used to complement mutagenesis techniques in order to further optimize the photoelectric response of the protein.

The architecture of many biomolecular devices utilizes organic macromolecules, specifically proteins, in the form of a dried film. Dried films of protein are less bulky than liquid or gel matrices and resistant to fluctuation in pH and temperature. In the case of BR, thin film fabrication must preserve the structure of the protein while optimizing the photoelectric characteristics. To preserve the structure and function of BR, the protein is isolated and deposited onto the substrate in the form of purple membrane patches. Purple membrane patches are approximately 5-nm thick and are primarily composed of BR molecules arranged in a hexagonal lattice of trimers. This architecture allows BR to absorb light in all polarizations while stabilizing the protein over a wide range of temperature and pH values. Such characteristics make purple membrane films ideal for biomolecular device applications.

2.8 Bacteriorhodopsin as a Sensor

Bacteriorhodopsin has been long known to display an extreme sensitivity to environment conditions such as pH, relative humidity, and ionic strength. The effects of this sensitivity can be manifested as modulations to the photocycle or photovoltaic effect. Furthermore, various chemicals have well-defined and well-characterized effects on the protein. One such class of chemical modulators is organic amines, which act to prolong the M intermediate. The M state decays as a function of the deprotonation

of Asp 96, and any environmental condition that favors reduced proton mobility will prolong this state, including, for example, high pH or dehydration. Organic amines also facilitate prolonged M states; at first glance, it might be expected that this is a pH-related affect, although given sample preparations with identical pH, those treated with organic amines exhibit more pronounced effects. The O state, also characterized by proton transfer, is similarly sensitive to the presence of environmental additives. The mechanisms that cause these responses are not well understood.

Other classes of chemicals that modulate the photophysical properties of BR include alcohols (methanol, ethanol, propanol, and butanol) and anesthetics. Azides are also known to modulate the photophysical properties of BR. Sensitivity of the protein to alcohols is manifested in the form of modulations of the light-induced photocurrent of the protein and could be enhanced by chemical modification of the chromophore or genetic manipulation of the protein. One plausible mechanism for the alcohol-induced sensitivity of BR is through local dehydration effects that essentially mimic reduced relative humidity. Numerous studies have demonstrated the effect of anesthetics on BR response, which exhibit several general modes of action. Anesthetics modify ion transport through membrane channels and thus are of interest with respect to the nervous system. The concentration-induced effects observed in BR consist of a slight initial blue shift (569–567 nm) to a state with an accelerated M state. Higher anesthetic concentrations result in a larger blue shift (480 nm), a prolonged M state, and a loss of both proton pumping function and the purple membrane lattice structure. Some anesthetics will produce a 380-nm absorbing species. At lower anesthetic concentrations, most effects were found to be reversible. X-ray studies indicate that anesthetics bind at the lipid protein interface in the center of a BR trimer. Other studies have posited distinct binding sites. Generally speaking, therefore, chemical agents have several modes by which they can modulate protein response, including direct interaction with, or binding to, the protein, and/or indirect interaction by absorption into the lipids proximal to the protein.

As indicated earlier, various chemical species have been used in the past to modulate the response of the protein to light by employing chemicals that modulate the M and O states. Although these attempts were targeted at developing photonic devices, they are indicative of the ability of this protein to respond to and register the state of the immediate environment. Furthermore, as detailed above, a wide variety of external molecular stimuli have proven to modulate the response of the protein, indicating the potential role BR might play as a chemical sensor in a hybrid protein-semiconductor architecture. Given the ability to interrogate the protein with light, signals can be extracted that are a reflection of the environment experienced by the protein. Such signals might result from a modulation of the photocycle kinetics, the photovoltaic effect, or a combination of both. Thus, by extension, it is possible to use either the photocycle kinetics or photovoltaic responsivity to monitor the concentration of volatile species present in the environment. It can be concluded that the complexity of BR photophysics and sensitivity to external molecular stimuli combine to make this protein a strong candidate for the design of hybrid protein-semiconductor sensors in detection schemes for chemical agents that are deleterious to human health, including environmental toxins, industrial

pollutants, and chemical warfare agents. Additionally, the ability to implement multiple interrogation techniques gives BR a unique advantage over other more conventional materials.

3 Other Proteins as Biomolecular Devices

Discussion so far has been limited to the optimization of BR. This emphasis is appropriate from a historical perspective because the vast majority of bioelectronic devices have involved the use of BR and BR variants. Nevertheless, there are many other proteins that are currently under investigation for device applications. Greenbaum and Boxer have investigated the use of photosynthetic proteins and reaction centers for device applications. These proteins exhibit high photoconversion efficiencies and intrinsic diodelike characteristics that are useful for a number of applications.

One might anticipate that the visual pigment rhodopsin would find device application, but the use of this protein poses a major problem that will not be easily solved. When the protein absorbs a photon of light, the chromophore is isomerized from 11-*cis* to all-*trans* and is expelled from the protein. In vivo, a complex enzymatic process regenerates 11-*cis* retinal that is transported back to the rod outer segment and spontaneously recombines with the protein to reform an active visual pigment. The cycle requires many minutes and would be extremely difficult to implement in a device environment. However, there are sources of rhodopsin that provide binary responses without chromophore expulsion. Many invertebrate proteins operate in this fashion and this avenue is worthy of further study. Proteorhodopsin, a recently discovered light-transducing protein from oceanic bacteria, shows significant potential for device applications. This protein shares many of the positive characteristics of BR while providing significant differences in the photocycle that may provide a comparative advantage in photonic devices. What remains is to improve the thermal stabilities and inherent lifetimes of these proteins when used in device environments. Not one of the above mentioned proteins could be used in high-temperature electronic systems. Directed evolution will play an important role in optimizing the thermal stability of candidate proteins.

4 Summary

Nature has been optimizing proteins for roughly three billion years, and many of the characteristics required of proteins to function in biology are identical to those required for device applications. Thus, natural materials are logical candidates for electronic and photonic devices. Nevertheless, virtually all device environments pose unique problems that require further optimization of biological molecules for the device to function at full potential. This chapter has provided an overview of these methods and procedures using the protein bacteriorhodopsin (BR) as the template. A key observation, however, is that BR is only one of many proteins that has potential for device applications. Bioelectronics is in a very early stage of making contributions to electronics and photonics, and only a small number of architectures have been explored. Genetic engineering and directed evolution will prove crucial to the full exploration and optimization of materials for bioelectronic application.

Keywords

Apoenzyme
A protein moiety of an enzyme that requires a coenzyme.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 9
Edited by Robert A. Meyers.

ISBN: 3-527-30551-3

Cofactor
A natural reactant, usually either a metal ion or coenzyme, required in an enzyme-catalyzed reaction.

Holoenzyme
A catalytically active enzyme constituted by coenzyme bound to apoenzyme.

Vitamin
An essential organic micronutrient that must be supplied exogenously and in many cases is the precursor to a metabolically derived coenzyme.

A coenzyme is an organic molecule that can bind within enzymes that require its function to catalyze a biochemical reaction. Hence, coenzymes are organic cofactors that augment the diversity of reactions that otherwise would be more limited to chemical properties of side chain substituents from amino acid residues within protein enzymes. Coenzymes bind to apoenzymes to generate catalytically competent holoenzymes. With tight binding, coenzymes may be referred to as prosthetic groups; with loose binding, they may be called *cosubstrates*.

1 General History

Most work on the chemical nature of coenzymes began in the 1930s, when elucidation of the structures of some vitamins in the B complex was being accomplished. In 1932, Auhagen had succeeded in dissociating a heat-stable component of yeast ''carboxylase,'' which he called ''cocarboxylase.'' By 1937, Lohmann and Schuster had determined its structure as thiamine pyrophosphate (TPP). Warburg and Christian were active in elucidating the nature of the oxidation–reduction coenzymes that contain riboflavin (FMN, FAD: see Sect. 2.1.2) and nicotinamide (NAD, NADP: see Sect. 2.1.3) during this same period. By the mid-1940s, the coenzyme forms of B_6 (PLP, PMP: see Sect. 2.1.4) were recognized by Gunsalus, Snell, and others. The discovery by Lipmann in 1947 of a coenzyme of acetylation (CoA), which contained pantothenate, led to the full structure elucidation by Baddiley et al. in 1953. Advances also made in the 1950s by a number of laboratories led to the recognition of coenzyme forms of folacin, and by the end of the decade, Lynen et al. had characterized covalent N^1-carboxybiotin and Barker and his associates had identified a coenzyme form of B_{12}. Prerequisite to determining structures of coenzymes were recognition and purification of enzyme systems that depend on the catalytic participation of these organic cofactors. Continued examinations of diverse enzymes are extending the list of newer coenzymes, some of which do not derive from vitamins.

2 Individual Coenzymes

2.1 Vitamin-derived Coenzymes

Many coenzymes are the metabolic result of converting ingested vitamins, especially those of the B complex, to forms suitable for binding and function in enzyme systems. Of the 13 vitamins presently known to be required in the diet of humans and most animals, at least eight (thiamine, riboflavin, niacin, vitamin B_6, folacin, vitamin B_{12}, biotin, and pantothenate) are simply the essential precursors for coenzymic forms made in the body. These coenzymes and their functions are listed in Table 1.

2.1.1 Thiamine Pyrophosphate

The pyrophosphate ester formed at the β-hydroxyethyl substituent in position 5 of the thiazole moiety of thiamine is the principle if not sole coenzyme derived from thiamine. TPP, as is the case with the parent vitamin, is relatively stable in acidic aqueous solutions, but sulfite causes cleavage at the methylene bridge to release the substituted pyrimidylsulfonate and the thiazole pyrophosphate. TPP is unstable in alkaline medium because the thiazole portion is subject to base attack at C-2. With hydroxyl ion, this leads to a pseudobase, thiazole ring opening, and some disulfide under mild oxidizing conditions. Also, the 4-amino on the pyrimidyl portion can attack as an intramolecular base to form the tricyclic amino adduct, which can be oxidized with ferricyanide to yield thiochrome pyrophosphate. The thiochrome-level compound is fluorescent (wavelengths of excitation and emission, 385 and 440 nm, respectively) and is easily detected.

TPP is formed in a number of tissues from thiamine, and a fraction is subsequently converted, especially in brain, to the triphosphate. Hydrolysis of the latter to the monophosphate and some further release of free vitamin occurs. Among the forms involved, TPP predominates in cells. About half the body stores are found in skeletal muscle, with much of the remainder in heart, liver, kidneys, and nervous tissue, including brain, which contains much of the triphosphate. Enzymes catalyzing the interconversions include thiaminokinase, which utilizes thiamine and adenosine triphosphate (ATP) to form TPP and adenosine monophosphate (5′-AMP). A phosphoryl transferase that seems to be adenylate kinase uses a second ATP to interconvert TPP to adenosine diphosphate (ADP) and thiamine triphosphate. A membrane-associated triphosphatase is found mainly in nervous tissue.

TPP functions as the Mg^{2+}-coordinated coenzyme for the so-called active aldehyde transfers in two general types of reaction involving attack of carbonyl metabolites by the carbanion generated at C-2 on the thiazole moiety of TPP (Fig. 1). First, in decarboxylation of α-keto acids, the condensation of the thiazole moiety of TPP with the α-carbonyl carbon on the acid leads to the loss of CO_2 and production of a resonance-stabilized carbanion. Protonation and release of aldehyde occur in fermentative organisms such as yeast, which have only the TPP-dependent decarboxylase, but reaction of the α-hydroxalkyl–TPP with lipoyl residues and ultimate conversion of acyl–CoA occur in higher eukaryotes, including humans, with multienzymic dehydrogenase complexes. A lyase that is required to shorten 3-methyl-branched fatty acids, for example, phytanic acid, by α-oxidation also requires TPP.

Tab. 1 Coenzymatic forms and functions of B vitamins.

Coenzyme forms	***Enzyme systems***	***Functions***
	Thiamine (B_1)	
Thiamine pyrophosphate (perhaps triphosphate)	α-Keto acid decarboxylases, transketolase	Decarboxylations of α-keto acids from metabolism of carbohydrates and amino acids; glycolaldehyde transfers; nerve membrane ion transport
	Riboflavin (B_2)	
Flavin mononucleotide, flavin–adenine dinucleotide (covalent and noncovalent)	Oxidases, dehydrogenases	Hydrogen atom transfers from substrates to oxygen and to cytochromes
	Niacin	
Nicotinamide adenine dinucleotide and the 2′-phosphate	Reductases, dehydrogenases	Hydride ion transfer
	Vitamin B_6	
Pyridoxal 5′-phosphate, pyridoxamine 5′-phosphate	Aminotransferases, amino acid decarboxylases, amino acid dehydratases, cystathionine synthetase, phosphorylase, 5-amino levulinate synthetase, etc.	Transaminations, decarboxylations, and side chain, cleavages of amino acids; breakdown of glycogen; biosynthesis of heme, phospholipid, etc.
	Folacin	
Tetrahydrofolate and γ-glutamyl conjugates	Transformylases, thymidylate synthetase, hydroxymethyltransferases, formiminotransferase, etc.	One-carbon activation and transfer as in purine and pyrimidine biosynthesis; catabolism of serine and histidine, etc.
	Vitamin B_{12}	
5′-Deoxyadenosylcobalamin	L-Methylmalonyl–CoA mutase	Isomerization of L-methylmalonyl–CoA to succinyl–CoA
Methylcobalamin	5-Methyltetrahydrofolate–homocysteine methyltransferase	Methyl group transfer as in methionine biosynthesis
	Biotin	
1′-*N*-Carboxybiotin as amide-linked to ε-lysyl residues	Acyl–CoA carboxylases and other bicarbonate-dependent carboxylases	CO_2 activation and transfer in formation of acids
	Pantothenic Acid	
CoA	Acyl transferases, etc.	Fatty acid metabolism, etc.
4′-Phosphopantetheine	Acyl carrier protein of fatty acid synthetase	Fatty acid biosynthesis

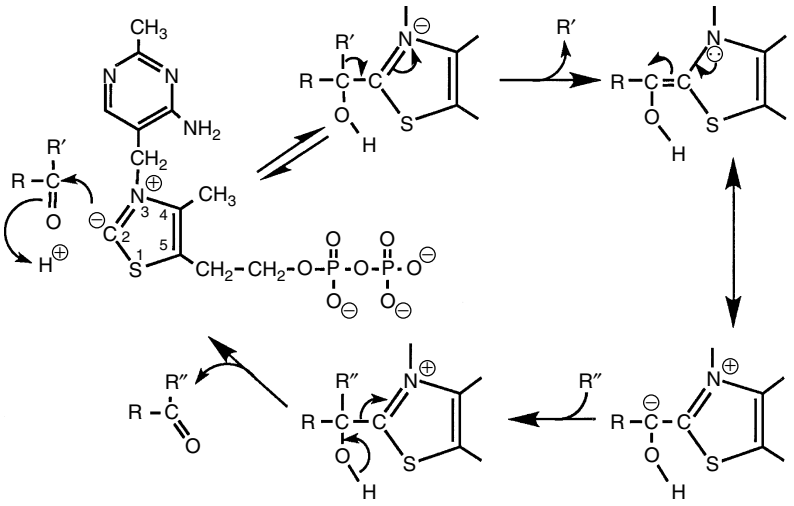

Fig. 1 Function of the thiazole moiety of TPP in α-keto acid decarboxylations (where R′ is a carboxylate lost as CO_2 and R″ is a proton generating an aldehyde) and in ketolations (where R′ is a carbohydrate moiety releasing a glycose and R″ is a different glycose generating a new carbohydrate).

The other general reaction involving TPP is the transformation of α-ketols (ketose phosphates). Although specialized phosphoketolases in certain bacteria and higher plants can split ketose phosphates to simpler, released products, the reaction of importance to humans and most animals is a transketolation. Transketolase is a TPP-dependent enzyme found in the cytosol of many tissues, especially liver and blood cells, where principal carbohydrate pathways exist. This enzyme catalyzes the reversible transfer of a glycoaldehyde moiety (α,β-dihydroxyethyl-TPP) from the first two carbons of a donor ketose phosphate to the aldehyde carbon of an aldose phosphate of the pentose phosphate pathway, which also supplies reduced nicotinamide adenine dinucleotide phosphate (NADPH) needed for biosynthetic reactions.

2.1.2 **Flavocoenzymes**

Structures of the natural flavocoenzymes, all containing a substituted tricyclic isoalloxazine nucleus derived from riboflavin, are given in Fig. 2. The monophosphate ester formed at the 5′-hydroxymethyl side chain substituent of riboflavin is a flavocoenzyme called flavin mononucleotide (FMN). It is the precursor to the more commonly occurring flavin adenine dinucleotide (FAD), which includes a pyrophosphoryl-linked 5′-AMP moiety extended from the phosphoryl function of FMN. In some less commonly encountered, but essential, forms of flavocoenzymes, there is covalent attachment of a peptidyl residue through an electronegative atom, usually in the 8α-position. Flavocoenzymes are relatively more stable in acid than in base and are photodecomposed, largely to lumichrome and lumiflavin, by cleavages at the ribityl side chain. In the natural oxidized (quinoid) forms, FMN and FAD are fluorescent (wavelengths of excitation and emittance, 450 and 530 nm, respectively) and are readily detected when unbound by protein; however, FAD is significantly quenched

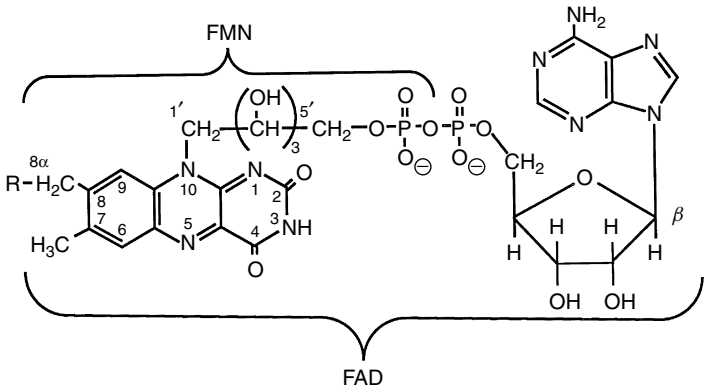

Fig. 2 Structure for principal flavocoenzymes where R = H for FAD or an electronegative atom (N, O, S) within a peptide side chain for covalently attached species.

by its intramolecular complex in solution. The observed oxidation–reduction potential near −0.2 V poises these coenzymes for electron transport, usually after (above) the more negative pyridine nucleotides and before (below) cytochromes.

Biosynthesis of flavocoenzymes occurs within the cellular cytoplasm of most tissues, but particularly in the small intestine, liver, heart, and kidney. The obligatory first step is the ATP-dependent phosphorylation of riboflavin catalyzed by Zn^{2+}-preferring flavokinase. The FMN product can be complexed with specific apoenzymes to form several functional flavoproteins, but the larger quantity is further converted to FAD in a second ATP-dependent reaction catalyzed by Mg^{2+}-preferring FAD synthetase. These coenzyme-forming steps are tightly regulated. FAD is the predominant flavocoenzyme present in tissues, where it is mainly complexed with numerous flavoprotein dehydrogenases and oxidases. Less than 10% of the FAD can also become covalently attached to specific amino acid residues of a few important apoenzymes. Examples include the 8α-*N*(3)-histidyl-FAD within succinate dehydrogenase and 8α-*S*-cysteinyl-FAD within monoamine oxidase, both of mitochondrial localization. Turnover of covalently attached flavocoenzymes requires intracellular proteolysis, and further degradation of the coenzymes involves a pyrophosphate cleavage of FAD to FMN and action by nonspecific phosphatases on the latter.

Flavocoenzymes participate in oxidation–reduction reactions in numerous metabolic pathways and in energy production via the respiratory chain. The redox functions of a flavocoenzyme (Fig. 3) include one-electron transfers during which the biologically encountered, neutral, oxidized quinone level of flavin is half-reduced to the radical semiquinone, which can exist within natural pH ranges as neutral or anionic species. A further electron can lead to a fully reduced hydroquinone. Additionally, a single-step, two-electron transfer from substrate to flavin can occur (Fig. 4). Such cases as hydride-ion transfer from reduced pyridine nucleotide or the carbanion generated by base abstraction of a substrate proton may lead to attack

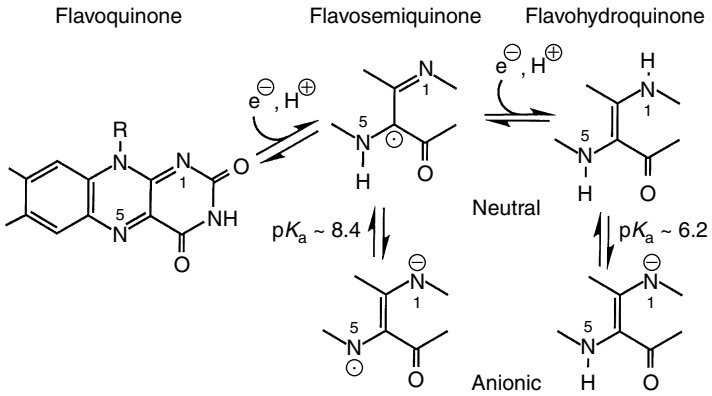

Fig. 3 Physiologically relevant redox states of flavocoenzymes with pK_a values estimated for interconversions of the free species.

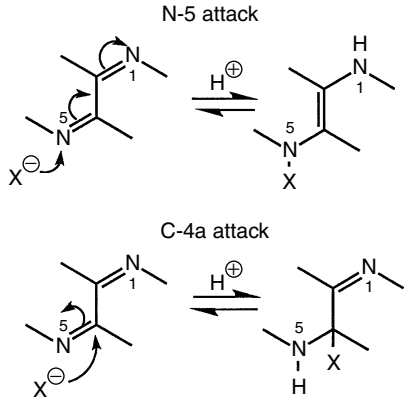
Fig. 4 Reaction types encountered with flavoquinone coenzymes and natural nucleophiles (X^-).



at the flavin at N-5; some nucleophiles such as the hydrogen peroxide anion add at C-4a.

There are flavoprotein-catalyzed dehydrogenations that are both pyridine nucleotide dependent and independent, reactions with sulfur-containing compounds, hydroxylations, oxidative decarboxylations, dioxygenations, and reduction of O_2 to hydrogen peroxide. The flavins are characterized by wide scope in their operation due to their intrinsic abilities to be varyingly potentiated as redox carriers upon differential binding to proteins, to participate in both one- and two-electron transfers, and, in reduced (1,5-dihydro) form, to react rapidly with oxygen.

2.1.3 **Pyridine Nucleotide Coenzymes**

Nicotinamide adenine dinucleotide and its phosphate (Fig. 5) are the two natural coenzymes derived from niacin. Both contain an N-1 substituted pyridine 3-carboxamide that is essential to function in redox reactions with a potential near −0.32 V. The oxidized coenzymes are labile to alkali, including nucleophilic addition at the para (4) position, whereas the reduced (1,4-dihydro) coenzymes are labile

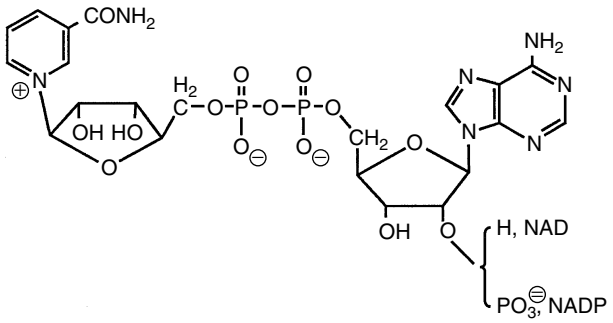


Fig. 5 Structures for pyridine nucleotide coenzymes.

to acid. Reduced coenzymes (NADH and NADPH) characteristically absorb light in the near-ultraviolet region (340 nm).

Converging pathways lead to the formation of NAD, a fraction of which is phosphorylated to NADP. Vitaminic precursors are converted to the coenzymes in blood cells, kidney, brain, and liver. Nicotinate and nicotinamide react with 5-phosphoribosyl-1α-pyrophosphate (PRPP) and nicotinic acid mononucleotide (NaMN) or nicotinamide mononucleotide (NMN), respectively. Additionally, in liver, quinolinate from catabolism of tryptophan is similarly converted, with concomitant decarboxylation to NaMN. Subsequent reactions with ATP to incorporate the 5′-adenylate portion yield NAD from NMN and deamido-NAD from NaMN. The deamido compound reacts with glutamine in a cytosolic-ATP-dependent step to yield NAD, glutamate, AMP, and pyrophosphate. In breakdown, NAD is hydrolyzed to NMN and the latter to nicotinamide, which, in turn, can be converted to nicotinate by a rather widespread microsomal deamidase. An NAD glycohydrolase (NADase) catalyzes hydrolysis of NAD to nicotinamide plus adenosine 5′-pyrophospho-5-ribose (ADPR). Some NAD glycohydrolases have the ability to transglycosidate (i.e. to transfer the ADPR moiety of NAD to acceptor macromolecules).

Numerous enzymes require the nicotinamide moiety within either NAD or NADP. Most of these oxidoreductases function as dehydrogenases and catalyze such diverse reactions as the conversion of alcohols (often sugars and polyols) to aldehydes or ketones, hemiacetals to lactones, aldehydes to acids, and certain amino acids to keto acids. The common mechanism of operation (generalized in Fig. 6) involves the stereospecific abstraction of a hydride ion from substrate, with para addition to one or the other side of C-4 in the pyridine ring of the nucleotide coenzyme. The second hydrogen of the substrate group oxidized is concomitantly removed as a proton and ultimately exchanged as a hydronium ion.

Most dehydrogenases utilizing NAD or NADP function reversibly. Glutamate dehydrogenase, for example, favors the oxidative direction, whereas others, such as glutathione reductase, catalyze preferential reduction. A further generality is that most NAD-dependent enzymes are involved in catabolic reactions, whereas NADP systems are more common to biosynthetic reactions. The additional function of NAD as a substrate for providing the ADPR moiety to modify macromolecules has

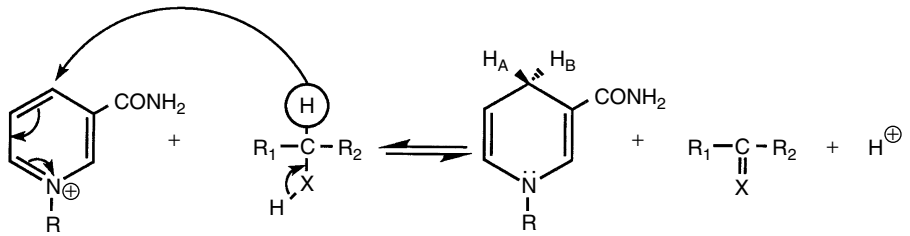

Fig. 6 The stereospecific hydride-ion transfer for operation of pyridine nucleotide coenzymes.

been recently more widely appreciated. ADP–ribosyl transferase catalyzes such a modification of the prokaryote elongation factor 2, thereby blocking translocation on ribosomes. Poly(ADPR) synthetases (polymerases) in eukaryotes catalyze a multiple addition of ADPR from NAD to form (ADPR) *n*-acceptor plus nicotinamide and hydrogen ion. This activity is found in mitochondria and bound to microsomes as well as in nuclei, where it affects the operation of DNA. This nonredox function of NAD probably accounts for the rapid turnover of NAD in human cells.

2.1.4 Pyridoxal 5′-phosphate and Pyridoxamine 5′-phosphate

Two of the three natural forms of vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine) can be phosphorylated to directly yield functional coenzymes; these are pyridoxal 5′-phosphate (PLP) and pyridoxamine 5′-phosphate (PMP). PLP is the predominant and more diversely functional coenzymic form, although PMP interconverts as coenzyme during transaminations. At physiological pH, the dianionic phosphates of these coenzymes exist as zwitterionic metaphenolate pyridinium compounds. They are very watersoluble, absorb light in the ultraviolet region, exhibit fluorescence, and, in general, are sensitive to light, particularly at alkaline pH. Both natural and synthetic carbonyl reagents (e.g. hydrazines and hydroxylamines) form Schiff bases with the 4-formyl function of PLP (and pyridoxal), thereby removing the coenzyme and inhibiting PLP-dependent reactions.

Each of the three vitamin-level compounds is phosphorylated in the cytosol by ATP-utilizing pyridoxal kinase, which, in mammalian tissues, prefers Zn^{2+}. Most cells of facultative and aerobic organisms contain a cytosolic, FMN-dependent pyridoxine (pyridoxamine) 5′-phosphate oxidase responsible for catalyzing the O_2-dependent conversion of pyridoxine 5′-phosphate (PNP) and PMP to PLP. During aminotransferase (transaminase)-catalyzed reactions, PLP and PMP interconvert with amino and keto functions of substrate–product participants. Release of free vitamin, mainly pyridoxal when physiological nonsaturating levels of vitamin are absorbed, occurs when the phosphates are hydrolyzed by nonspecific alkaline phosphatase located on the plasma membrane of cells.

PLP functions in numerous reactions that embrace the metabolism of proteins, carbohydrates, and lipids. Especially diverse are PLP-dependent enzymes that are involved in amino acid metabolism. By virtue of the ability of PLP to condense its 4-formyl substituent with an amine, usually the α-amino group of an amino acid, to form an azomethine (Schiff base) linkage, a conjugated double-bond system extending from the α-carbon of the amine (amino

acid) to the pyridinium nitrogen in PLP results in reduced electron density around the α-carbon. This reduction potentially weakens each of the bonds from the amine (amino acid) carbon to the adjoined functions (hydrogen, carboxyl, or side chain). A given apoenzyme then locks in a particular configuration of the coenzyme–substrate compound such that maximal overlap of the bond to be broken will occur with the resonant, coplanar, electron-withdrawing system of the coenzyme complex. These events are depicted in Fig. 7. Aminotransferases effect rupture of the α-hydrogen bond of an amino acid with ultimate formation of an α-keto acid and PMP; this reversible reaction provides an interface between amino acid metabolism and that for ketogenic and glucogenic reactions. Amino acid decarboxylases catalyze breakage of the α-carboxyl bond and lead to irreversible formation of amines, including several that are functional in nervous tissue (e.g. epinephrine, norepinephrine, serotonin, γ-aminobutyrate). The biosynthesis of heme depends on the early formation of δ-aminolevulinate from PLP-dependent condensation of glycine and succinyl–CoA followed by decarboxylation. There are many examples of enzymes, such as cysteine desulfhydrase and serine hydroxymethyltransferase, that affect the loss or transfer of amino acid side chains. PLP is the essential coenzyme for phosphorylase that catalyzes phosphorolysis of the α-1,4-linkages of glycogen. An important role in lipid metabolism is the PLP-dependent condensation of L-serine with palmitoyl–CoA to form 3-dehydrosphinganine, a precursor of sphingolipids.

2.1.5 Pterin Coenzymes

Among natural compounds with a pteridine nucleus, those most commonly encountered are derivatives of 2-amino-4-hydroxypteridines, which are trivially named pterins. Although a number of pterins when reduced to the 5,6,7,8-tetrahydro level function as coenzymes, the most generally utilized are poly-γ-glutamates of tetrahydrofolate (THF). These and their natural derivatives of tetrahydropteroylglutamates responsible for vectoring one-carbon units in different enzymic reactions are shown in abbreviated form in Fig. 8. All these pterins bear the substituent for transfer at N-5 or N-10 or are bridged between these basic centers. The number of glutamate residues varies, usually from one to seven, but a few to several glutamyls optimize binding of tetrahydrofolyl coenzymes to most enzymes requiring their function. Less commonly encountered,

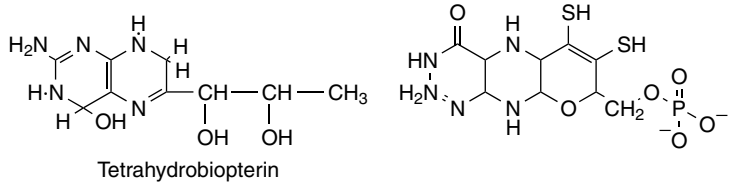

Fig. 9 Other pterin coenzymes: tetrahydrobiopterin of phenylalanine hydroxylase and the pterin cofactor of certain Mo/Fe flavoproteins.

but essential for some coenzymic roles of pterins, are the compounds shown in Fig. 9. Tetrahydrobiopterin cycles with its quinoid 7,8-dihydro form during O_2-dependent hydroxylation of such aromatic amino acids as in the conversion of phenylalanine to tyrosine. Tetrahydrobiopterin also serves as a one-electron donor in NO synthase catalysis. The recently elucidated molybdopyranopterin functions in some Mo/Fe flavoproteins such as xanthine dehydrogenase. Pterin coenzymes, most at the tetrahydro level, are sensitive to oxidation and have characteristic absorbance in ultraviolet light. Upon heating in aqueous media below pH 4, the pterin portion of the folyl-type coenzyme tends to split from the *p*-aminobenzoyl glutamate portion. The xanthine dehydrogenase pterin during isolation loses hydrogen from the side chain to generate a double bond between sulfur-bearing carbons.

The interconversions of folate with the initial coenzymic relatives, the tetrahydrofolyl polyglutamates, involve dihydrofolate reductase necessary for reducing the vitamin-level compound through 7,8-dihydro to 5,6,7,8-tetrahydro levels. This enzyme is the target of such inhibitory drugs as aminopterin and amethopterin (methotrexate). A similar dihydropterin reductase catalyzes reduction of dihydro- to tetrahydrobiopterin. Tetrahydrofolate is intracellularly trapped and extended to polyglutamate forms that operate with THF-dependent systems. In some cases (e.g. thymidylate synthetase), there is a redox change in tetrahydro to dihydro coenzyme, which is recycled by the

NADPH-dependent reductase. Turnover of coenzyme to folate at the monoglutamate level requires hydrolytic cleavage of the extra glutamyl residues. Cells of the small intestinal mucosa are especially rich in the γ-glutamyl peptidase ("conjugase") that degrades ingested natural folyl polyglutamates to the more readily absorbed folate.

Some of the major interconnections among one-carbon-bearing THF coenzymes and their metabolic origins and the roles are as follows:

1. Generation and utilization of formate.
2. *De novo* purine biosynthesis wherein glycinamide ribonucleotide and 5-amino-4-imidazole carboxamide ribonucleotide are transformylated by 5,10-methenyl-THF and 10-formyl-THF respectively.
3. Pyrimidine nucleotide biosynthesis, wherein deoxyuridylate and 5,10-methylene-THF form thymidylate and dihydrofolyl coenzyme.
4. Conversions of some amino acids, namely, *N*-formimino-L-glutamate (from histidine catabolism) with THF to L-glutamate and 5,10-methenyl-THF (via 5-formimino-THF), L-serine with THF to glycine and 5,10-methylene-THF, and L-homocysteine with 5-methyl-THF to L-methionine and regenerated THF.

2.1.6 B_{12} Coenzymes

The coenzyme B_{12} (CoB_{12}), known to function in most organisms, including humans, is 5′-deoxyadenosylcobalamin (Fig. 10). A second important coenzyme form is methylcobalamin (methyl-B_{12}), in which the methyl group replaces the deoxyadenosyl moiety of CoB_{12}. Some prokaryotes utilize other bases (e.g. adenine) in this position originally occupied by the cobalt-coordinated cyanide anion in cyanocobalamin, the initially isolated form of vitamin B_{12}. Coenzyme forms of B_{12} are light-absorbing, photolabile compounds that readily undergo photolysis to yield aquocobalamin (B_{12b}), in which H_2O is coordinated to cobalt in the corrin ring. Acid hydrolysis of CoB_{12} yields hydroxocobalamin (B_{12a}) with a coordinated hydroxyl ion.

The metabolic interconversions of vitamin B_{12} as the naturally occurring hydroxocobalamin (B_{12a}) with other vitamin- and coenzyme-level forms involves sequentially reduction of B_{12a} to the paramagnetic or radical B_{12r} and further to the very reactive B_{12s}. The latter reacts in enzyme-catalyzed nucleophilic displacements of tripolyphosphate from ATP to generate CoB_{12}, or of THF from 5-methyl-THF to generate methyl-B_{12}.

Seemingly CoB_{12}-dependent reactions proceed through a radical mechanism, and all but one (*Lactobacillus leichmanii* ribonucleotide reductase) involve a rearrangement of a vicinal group (X) and a hydrogen atom. This general mechanism is illustrated in Fig. 11. For the CoB_{12}-dependent mammalian enzyme, L-methyl-malonyl-CoA mutase, X is the CoA−S−CO−group, which moves with retention of configuration from the carboxyl-bearing carbon of LR-methylmalonyl−CoA to the carbon that lies beta to the carboxyl group in succinyl−CoA. This reaction is essential for funneling propionate to the tricarboxylic acid cycle. Without CoB_{12} (from vitamin B_{12}), more methylmalonate is excreted, but also the CoA ester competes with malonyl−CoA in normal fatty acid elongation to form instead abnormal, branched-chain fatty acids. Methyl-B_{12} is necessary in the transmethylase-catalyzed formation of L-methionine and regeneration of THF. Without this role, not only would there

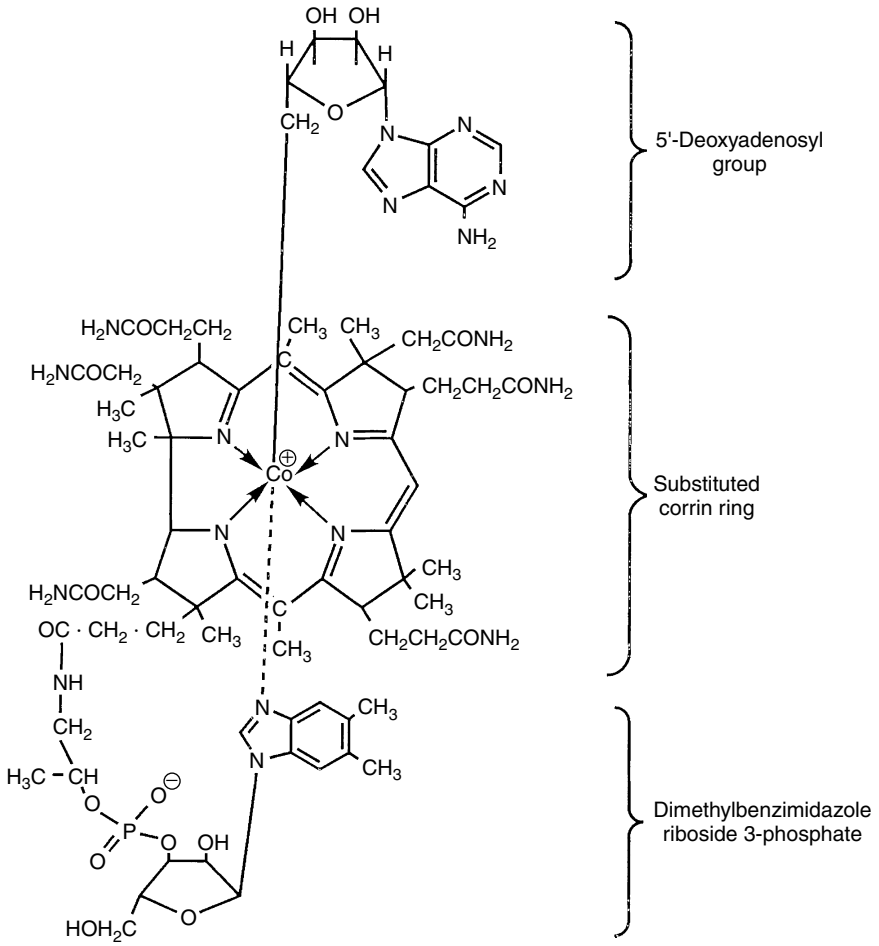

Fig. 10 Structure with identification of principal components for coenzyme B_{12}.

be impaired biosynthesis of the essential amino acid but increased exogenous supply of folate would be necessary to replenish THF, which would not otherwise be recovered from its 5-methyl derivative.

2.1.7 **Biotinyl Functions**

The coenzymic form of biotin occurs naturally only as the vitamin that is amide-linked to the ε-amino group of specific lysyl residues in carboxylases and transcarboxylase (Fig. 12). Though the two ureido nitrogens are essentially isoelectronic in the biotinyl moiety, the steric crowding of the thiolane side chain near N-3′ essentially prevents chemical additions, which therefore occur at N-1′.

Biotin is inserted into enzymes dependent on its operation by a holoenzyme synthetase that forms biotinyl 5′-adenylate as an intermediate from the vitamin and ATP. Usual proteolytic turnover of biotinylated enzymes release biocytin (ε-N-biotinyl-L-lysine), which is further hydrolyzed to

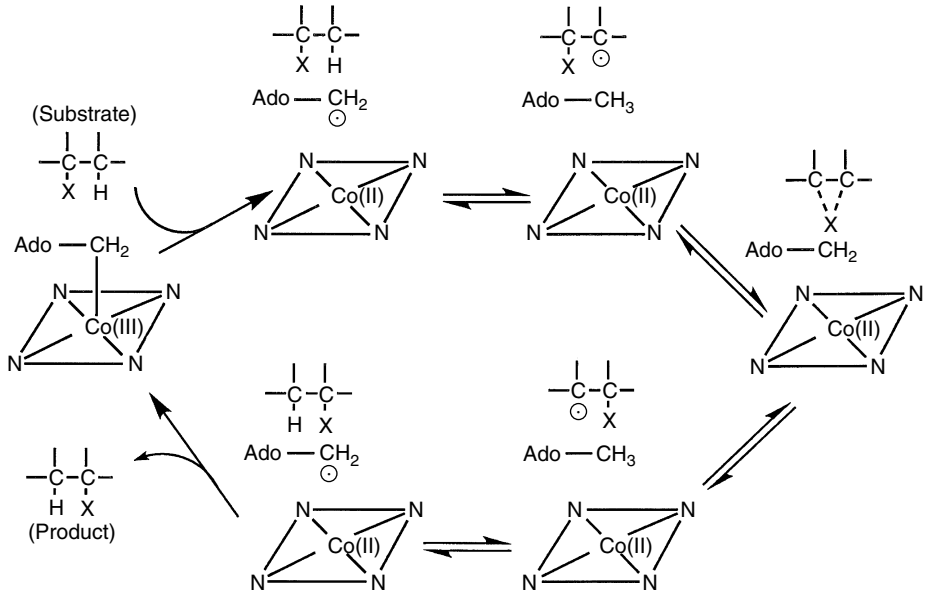

Fig. 11 Radical intermediates in Co-B_{12} enzyme reactions. Ado, adenosine.

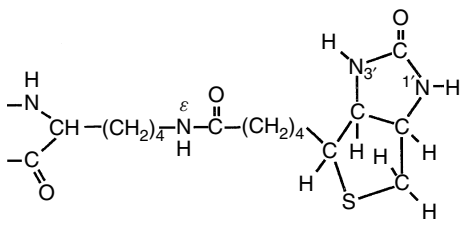

Fig. 12 Structure of the *d*-biotinyl-L-lysyl coenzyme moiety.

release the vitamin and amino acid in a reaction catalyzed by biotinidase (biocytinase, biotin amidohydrolase).

There are nine known biotin-dependent enzymes: six carboxylases, two decarboxylases, and a transcarboxylase. Of these, only four carboxylases are found in tissues of humans and other mammals. These carboxylases, named for their substrates, are (1) a cytosolic enzyme that converts acetyl–CoA to malonyl–CoA for fatty acid biosynthesis, (2) a mitochondrial enzyme that converts pyruvate to oxalacetate for citrate formation, (3) the enzyme for converting propionyl–CoA to D-methylmalonyl–CoA, and (4) the enzyme that carboxylates β-methylcrotonyl–CoA from L-leucine catabolism to form β-methylglutaconyl–CoA. Biotin-dependent carboxylases operate by a common mechanism (Fig. 13). This involves phosphorylation of bicarbonate by ATP to form carbonyl phosphate, followed by transfer of the carboxyl group from this electrophilic mixed-acid anhydride to the sterically less hindered and nucleophilically enhanced N-1′ of the biotinyl moiety. The resulting N(1)′-carboxybiotinyl enzyme can then exchange the carboxylate function with a reactive center in a substrate, typically at a carbon with incipient carbanion character.

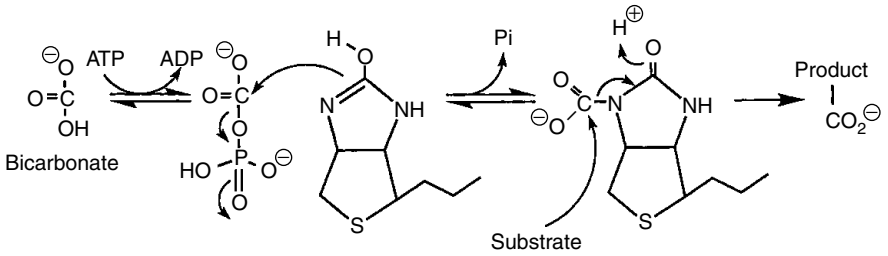

Fig. 13 Mechanism of carboxylations by biotin-dependent enzymes with the intermediacy of the putative carbonyl phosphate.

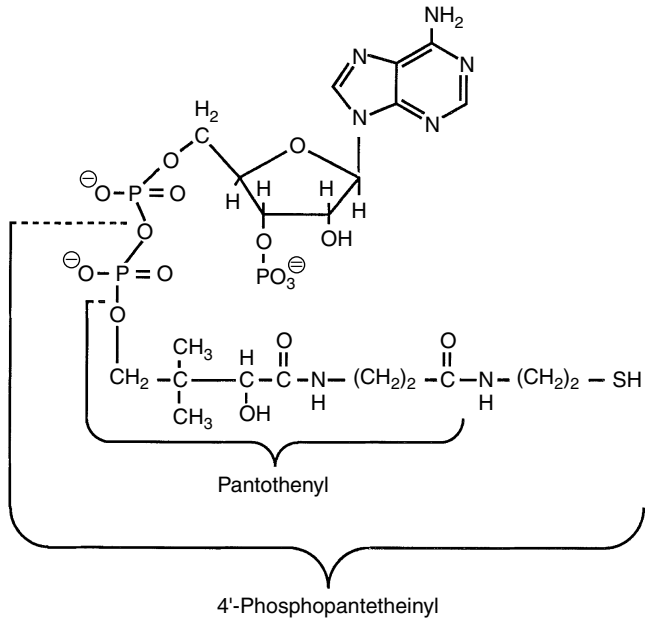

Fig. 14 Structure for coenzyme A with pantothenyl and 4′-phosphopantetheine as components.

2.1.8 **Phosphopantetheinyl Coenzymes**

The 4′-phosphopantetheinyl moiety, derived from the vitamin pantothenate and β-mercaptoethylamine, serves as a functional component within the structure of coenzyme A (Fig. 14) and as a prosthetic group covalently attached to a seryl residue of acyl carrier protein (ACP). Because of the thiol terminus with a pK_a near 9, phosphopantetheine and its coenzymic forms are readily oxidized to the catalytically inactive disulfides. CoA has a strong absorption maximum at 260 nm, attributable to the adenine moiety.

Within cells, synthesis of CoA and the 4′-phosphopantetheinyl moiety of ACP occurs via successive enzyme-catalyzed conversions from pantothenate to its 4′-phospho derivative to 4′-phosphopantothenyl-L-cysteine followed by decarboxylation to 4′-phosphopantetheine, which gains the AMP portion

to form dephospho–CoA. This latter is phosphorylated to form CoA. Following the ATP-driven steps in biosynthesis of CoA, formation of ACP occurs by transfer of the 4′-phosphopantetheinyl moiety of CoA, which binds via a phosphodiester link to apo-ACP in a reaction catalyzed by ACP holoprotein synthetase. About 80% of pantothenate in animal tissues is in CoA form, much of it as thioesters. The rest exists mainly as phosphopantetheine and phosphopantothenate. Cleavage enzymes catalyzing hydrolysis of the phosphate moieties (CoA → dephospho–CoA → 4′-phosphopantetheine → pantetheine) and release of β-mercaptoethylamine (cysteamine) and pantothenate from pantetheine operate during turnover and release of the vitamin, some of which is excreted in urine.

The myriad acyl thioesters of CoA are central to the metabolism of numerous compounds, especially lipids and the ultimate catabolic disposition of carbohydrates and ketogenic amino acids. The chemical properties of the thioester, which has a high group-transfer potential, permits facile acylations and hydrolysis; the ready formation of enolate ions and the carbanionlike character of the carbon α to the carbonyl facilitate condensation reactions. For example, acetyl–CoA, which is formed during metabolism of carbohydrates, fats, and some amino acids, can acetylate compounds such as choline and hexosamines to produce essential biochemicals; it can also condense with other metabolites such as oxalacetate to supply citrate, and it can lead to cholesterol. The reactive sulfhydryl termini of ACP provide exchange points for acetyl–CoA and malonyl–CoA. The ACP–S-malonyl thioester can chain-elongate during fatty acid biosynthesis in a synthetase complex.

2.2 Other Coenzymes

There are a growing number of coenzymes that are not formed from vitamins and hence can be biosynthesized by at least most of the organisms that require them. Sections 2.2.1 through 2.2.5 briefly describe several additional coenzyme types.

2.2.1 Pyruvoyl Functions

A simpler, but less frequently encountered variation on one way in which pyridoxal 5′-phosphate operates is provided by the pyruvoyl N-terminus of some enzymes. In these electrophilic centers, the amino function of a substrate amino acid condenses to form a ketimine, which facilitates loss of a carboxyl group from the attached amino acid moiety. For example, *S*-adenosylmethionine decarboxylases from mammals as well as from *Escherichia coli* use such a subsystem to form spermidine from putrescine and methionine.

2.2.2 Lipoyl Functions

α-Lipoic (thioctic) acid occurs naturally in amide linkage to the ε-amino group of lysyl residues within transacylases that are core protein subunits of α-keto acid dehydrogenase complexes. In such cases, the functional dithiolane ring is on an extended flexible arm. The lipoyl function mediates the transfer of the acyl group from α-hydroxylalkyl–TPP to CoA in a cyclic system that transiently generates the dihydrolipoyl residue.

2.2.3 Ubiquinones

The ubiquinones (coenzyme Qs) are a group of ''ubiquitous'' substituted benzoquinones with variable-length terpenoid chains. In eukaryotes, they are found

mainly in the mitochondrial inner membrane, where they function to accept electrons from several different dehydrogenases and relay them to the cytochrome system. In this process, the quinone function can be cyclically reduced and reoxidized. Evidence has been found for a function of CoQ in plasma membrane electron transport, which influences mammalian cell growth.

2.2.4 Pyrroloquinoline Quinone and Quinoproteins

Pyrroloquinoline quinone (PQQ) is a coenzyme originally isolated from bacteria possessing a methanol dehydrogenase. PQQ functions as a redox component of holoenzymes in which the coenzyme can be reduced in some cases by successive one-electron steps to the radical and dihydro forms and in other cases directly to the dihydro level by two-electron processes. More recent detailed examinations of several quinoproteins have elucidated other quinone/hydroquinone-related coenzymes as side chain-altered prosthetic groups. Examples include the 6-hydroxydopa (trihydroxyphenylalanyl) residue at the active site of serum amine oxidase and the tryptophan tryptophylquinone in a bacterial methylamine dehydrogenase.

2.2.5 Methanogen Coenzymes

A diverse group of coenzymes is required to convert carbon dioxide to methane. These rather novel compounds vary from a complex nickel-porphyrin–like F_{430} to the phenyl ether of methanofuran, the unusual pterin of tetrahydromethanopterin, and the deazaflavin of F_{420}, to the somewhat simpler sulfur-containing mercaptoheptanoylthreonine and coenzyme M. These are used by highly specialized Archaebacteria (known as *methanogens*) that can accomplish the reduction of CO_2 through formyl, methyl, methylene, and methyl stages of CH_4. The importance of the coenzymes that participate can be appreciated by the quantitative and global aspects of carbon cycling through methane-forming systems, which are not only free-living microbes but also are found in microbes in the human intestinal tract.

Keywords

Chiral Molecules
A molecules that is not superimposable on its mirror image. The two molecules (enantiomers) have identical physical properties with the exception of their interactions with other chiral molecules or with chiral radiation (e.g. plane or circularly polarized light). A racemic mixture contains equal amounts of each enantiomer.

Hydrothermal Systems
The circulation of seawater near the hot magma at a sea floor spreading to the center formed as a result of plate tectonics. This circulation results in heating of the water to 300–400 °C and the reduction of compounds in the seawater (e.g. $SO_4^=$ to S^-) and the deposition of metal sulfides and other reduced metal derivatives proximate to the spreading center.

Peptide Nucleic Acid (PNA)
A polymer composed of repeating β-amino acids with attached nucleic acid bases that are proposed to have been precursors to the RNA world. The nucleic-acid bases are attached to the polymer at the same distance apart as the bases in DNA and RNA so that PNA is able to form double helices with both these nucleic acids.

Ribozyme
An RNA that catalyzes reactions.

RNA World
A proposed early stage in the formation or evolution of primitive life in which RNA was the principal biopolymer. The RNA world is proposed to be the precursor to the DNA/protein world of contemporary life.

Template-directed Synthesis
The synthesis of a complementary RNA or DNA by condensation of mononucleotides on a preformed RNA or DNA template. The sequence of the synthesized chain is determined by Watson–Crick hydrogen bonding between the mononucleotides and the complementary bases on the template.

Vesicle or Liposome
An approximately spherical body with a wall that is composed of long chain hydrocarbons with polar terminal groups. It contains an aqueous phase inside which may contain organic and inorganic substances.

Research on the origins of life is an investigation of the reaction pathways that start from simple organic molecules and end with the complex macromolecular structures that organized into the first life. The understanding of this evolution of chemical complexity requires information from astronomy, geology, biology, chemistry, and physics. For example, astronomy, geology, and physics provide data on the formation and environment of the early Earth. Information on reaction processes that led to the first self-replicating system comes from the disciplines of chemistry and biology.

1 Introduction

1.1 Formation of the Solar System

The processes leading to the origins of life were initiated 13.7 billion years ago (bya) with the Big Bang. The Big Bang has been described as the simultaneous appearance of plasmas of primary particles everywhere in the Universe. Element formation began almost immediately with the appearance of the elements hydrogen, helium, lithium, and beryllium by the combination of protons and neutrons. The subsequent star formation resulted in a higher density and temperature of these elements, which enabled the fusion of three atoms of helium to form carbon. Once carbon formed, all the other major biogenic elements formed from it including N, O, and P up to ^{58}Fe occurred. Further fusion to the higher elements was energetically unfavorable and did not occur until stars used up all their H and He at which point the star collapsed catastrophically and then exploded into a supernova; this provided the energy to form the heavier elements as it blew them out into space during the explosion.

Some ''carbon stars'' with high abundances of carbon contribute large amounts of carbon into the interstellar medium when they explode. Interstellar dust clouds are composed of carbon and silicate dust. Chemistry takes place in these dust clouds,

driven mainly by cosmic rays, which enhances the chemical complexity of the carbon compounds. These dust clouds have lifetime of $10^7 - 10^8$ years. They collapse due to the effect of external forces (e.g. nearby supernovae), and star and planet formation takes place. During the process of collapse, the bulk of the mass forms a protostar that gets sufficiently hot to initiate nuclear fusion. A protoplanetary disk forms around the protostar during the collapse process that is composed of mass that became a part of the star. Here a localized area of gravitational collapse occurred, which eventually led to the formation of the planets, asteroids, and comets. Further accretion of the planets still is taking place today but at a much slower rate than when the planets were formed.

Since there is a direct connection between the origin of life and the formation of stars and solar systems, research on the origins of life requires knowledge of interstellar and stellar processes. Thus, studies on the origins of life is a truly interdisciplinary area with important contributions by astrophysicists, planetary geologists, chemists, and biochemists working together to trace a coherent pathway to the first life starting from the Big Bang.

1.2 The Nature of Life

What is life? How would one recognize a very primitive form of our ancestors? There is no consensus as to the basic requirements of the first living system. Does it require metabolic machinery or will the requisite metabolites be available for direct use? Will this life require the equivalent of a cell membrane or could it have been an assemblage of polymers bound to a rock? The diversity of opinion in the scientific community is illustrated by an informal poll. Most scientists agree that the first life should be able to replicate and evolve, which implies the presence of informational biomolecules that can be copied. This may be possible for an assemblage of polymers bound to a rock. Robots or even astronauts may have difficulty recognizing primitive life forms on other planetary bodies. It will be even more difficult to recognize life that uses a biochemistry very different from the one present on Earth.

1.3 The Earliest Life on Earth

Contemporary life is the result of about 4 billion years of evolutionary development and undoubtedly differs appreciably from the first life on Earth. There is little hope of detecting the original life forms today because the environment of the Earth has changed and the inefficient early life forms could not have competed with the highly evolved life present on Earth today.

There is a small possibility that life exists elsewhere in our solar system. Water is of central importance to life on Earth and there are several bodies in our solar system where water has been detected. There is ample evidence of ice being present on Mars. Channels, characteristic of flowing water, and lakebeds have been identified here. Ice has also been detected below the surface of Mars. Thus, it is possible that simple life forms live below the surface of Mars today. The other possible locations for existence of life are Europa, Ganymede and Callisto, the moons of Jupiter. There is evidence for liquid water below the icy surfaces of these three moons, so there is also the potential for life there as well.

Fossils of microorganisms, believed to have been present on the Earth

3.4–3.5 billion years ago (bya), have been found in Africa and Australia. Exhaustive radioactive dating provides firm evidence for the age of the rocks in which these fossils were found. The morphology of these multicellular microfossils does not establish the biochemistry utilized by these life forms.

Indirect evidence suggests that life was present on Earth prior to the 3.5 bya microfossils. This evidence is in the carbon isotope ratios observed in old rock formations. When CO_2 is reduced to carbohydrates by photosynthesis, it generates a product that contains a higher $^{12}C/^{13}C$ ratio than was present before photosynthesis. This isotope signature is seen almost all the way back to 3.8 bya suggesting the presence of life forms that carried out photosynthesis.

1.4 Environments on the Early Earth

The possible presence of photosynthetic life on the Earth 3.8 bya indicates it was a complex life form and suggests that primitive life may have been present on Earth closer about 4 bya. These data are in conflict with lunar crater data that suggests that the moon and hence the Earth also underwent a massive bombardment 3.9 bya that might have killed all the life on Earth. If this is correct, then photosynthetic life must have arisen rapidly in 0.1–0.2 bya. Alternatively, if the 3.9-bya bombardment did not sterilize the Earth, then life may have arisen around 4.2–4.4 bya when the bombardments decreased in intensity and the Earth cooled enough for oceans to form, and was more hospitable for life.

The early rock record on the Earth is fragmentary but what is known is consistent about the presence of liquid water 3.8 bya. Sedimentary rocks, in the Isua Formation in Greenland, were present at that time, so it is likely that water was present. The absence of rocks formed before 3.8 bya and that had not undergone major thermal alteration by plate tectonics make it almost impossible to determine the nature of the primitive Earth in earlier times.

The geology of the Isua rock formation suggests that the temperature of the early Earth was generally in the 0–100 °C range. Less is known concerning the chemical composition of the atmosphere. Initially it was thought that the atmosphere was reducing, containing large amounts of methane, ammonia, and molecular hydrogen. Then it was recognized that methane and ammonia would have undergone rapid photochemical destruction by ultraviolet light and the hydrogen formed would have escaped from the top of the atmosphere. The probable absence of reduced organic compounds, like methane, is supported by measurements of the oxidation level of the Earth's crust and mantle from the present back to 3.8 bya. It was determined from the investigations of rocks of these former eras that the oxidation state of the crust and mantle is the same now as it was 3.8 bya. The high oxidation state of the crust today results in the emission of oxidized organics and inorganic compounds by volcanoes. The same oxidized gases might have been given off 3.9 bya because the oxidation state of the crust and mantle has not changed. Thus, it is unlikely that the reduced compounds necessary for the origin of life were present 3.8 bya. If life originated at an earlier time, say 4.2–4.4 bya, there exists the possibility that there was a reducing atmosphere at that time. If life originated then, it would have had to survive the increased impacts that took place 3.9 bya.

The current model for the primitive atmosphere is that it had large amounts of molecular nitrogen and carbon dioxide and much smaller amounts of reduced carbon and nitrogen compounds. This view is consistent with the predominantly carbon-dioxide atmospheres of Venus and Mars, the two planets closest to the Earth in the solar system. The molecular oxygen in the Earth's atmosphere is a direct result of photosynthesis, hence the presence of life.

No strong data exist for the chemical pathways leading to the origins of life. It has not been possible to do a meaningful chemical analysis of the fossilized microscopic life forms in ancient rocks because most of the organic material has been replaced or extensively metamorphosed. Since biological evolution proceeds from simpler to more complex life, it is assumed that the chemical evolution leading to the first life also proceeded from simpler molecules to more complex biological polymers.

The absence of data concerning the earliest life on Earth means that it will not be possible to prove that any laboratory model of the origins of life is an exact representation of the earliest life on Earth. Consequently, experiments on the origins of life will be considered to be successful only if systems can be developed that undergo replication, mutation, and catalysis, and may conceivably have been present on the primitive Earth. It should be noted that development of these replicating and mutating systems would be a major scientific accomplishment because chemical systems of this complexity have not been developed previously. Consequently, this research will not only provide insight into the origin of life but it will also generate new ways to synthesize complex organic structures using simple reactants.

2 Reaction Conditions on the Primitive Earth

The Earth underwent rapid change in the 4.5–4.0 bya time period. The crust, initially molten, solidified, and when it had cooled below 100 °C, the oceans formed. Internal heat was released through the crust by extensive volcanic eruptions, which discharged the gases trapped or chemically combined in the crust into the atmosphere. The atmosphere of the early Earth is generally believed to have consisted mainly of N_2, CO_2, and water vapor. Reduced gases, such as CH_4, NH_3, CO, and H_2, were present only if their rates of release from the crust exceeded their rates of photolysis by ultraviolet light. Oceans were probably slightly acidic owing to the carbonic acid formed by dissolution of atmospheric CO_2. Basic minerals and traces of NH_3 would have converted some of the carbonic acid to bicarbonate. The rate of precipitation of $CaCO_3$ and $MgCO_3$ determined how long the pH of the oceans was controlled by a carbonic acid–carbonate buffer system. The concentrations of metal ions in the oceans probably were different from those present today. The alkali metal ions, calcium and magnesium, were present in about the concentrations found today, and the absence of molecular oxygen in the atmosphere suggests that the soluble lower oxidation states of many of the transition metals were also present. In fact, the presence of Fe^{2+} is demonstrated by the banded iron formations in the ancient rock record. It is believed that these iron oxide deposits were caused mainly by the oxidation of Fe^{2+} to insoluble Fe^{3+} compounds by the molecular oxygen produced by photosynthesis.

Some of the insoluble minerals may have been different from those found

today. For example, sulfides and cyanide complexes may have formed in the absence of molecular oxygen. The mineral surfaces probably served as important catalysts for prebiotic chemical processes. The energy required to drive prebiotic processes came principally from solar radiation, but crustal radioactivity and internal heat from the Earth may have also been important. Solar energy manifested itself on the Earth in the form of UV and visible light, lightning discharges, and heat. The Earth's internal heat resulted in high crustal temperatures and frequent volcanic eruptions; magma injected into the crust under the sea generated hydrothermal systems.

The general reaction conditions, which are believed to have been present over much of the primitive Earth, are described above. Just as there exists special niches of unusual temperature, acidity, mineralogical, or atmospheric conditions on the present Earth, it is likely that similar niches were present on the primitive Earth. We cannot exclude the possibility that some important processes of chemical evolution were triggered in one of these special environments. For example, a heterotrophic form of life may have originated in one of the niches where in a photosynthetic autotrophy evolved. Once it had developed the capability to make its own nutrients, it may have been able to survive under the global conditions outside this special environment.

3
Possible Sources of Simple Organic Compounds

3.1
The Earth's Atmosphere

Stanley Miller's production of amino acids by passing an electric discharge through a mixture of methane, ammonia hydrogen, and water vapor in 1953 was a dramatic demonstration that it is possible to carry out laboratory studies of the origins of life. In this famous experiment, Miller generated hydrogen cyanide (HCN), aldehydes, ketones, and hydroxy acids, along with a large array of amino acids. It was recognized that the large proportions of methane, ammonia, and hydrogen present in the gas mixture he used were inconsistent with the rapid loss of these gases from the Earth's atmosphere. In studies of the action of electric discharges on gaseous mixtures that contain smaller percentages of reduced organics and N_2 gas, Miller observed that hydrogen cyanide was the principal reaction product. Nitrogen oxides (NO, NO_2) are the reaction products if no hydrogen or reduced carbon or nitrogen compounds were present in the sparked mixture. The lower yields of organic substances in these discharge experiments prompted the search for other sources of organic compounds.

3.2
Interstellar Organic Molecules

Interstellar organic molecules are believed to be formed by the action of cosmic rays and UV light on the carbonaceous material

Tab. 1 Some interstellar organic compounds.

injected into space by the explosion of stars. The action of UV light is mainly effective in diffuse dust clouds while cosmic rays penetrate both dark and diffuse interstellar dust clouds. UV light is emitted by hot cores in dark clouds and is driven by the UV emission of a proximate protostar. The higher temperature of the protostar also warms the nearby dust grains and volatilizes the compounds condensed on them. Some of the volatile organic and inorganic molecules, radicals and ions identified by microwave spectroscopy are shown in Table 1.

3.3 Meteorites and Comets

The accretion of the Earth resulted from the impacts of smaller bodies on the Earth for several thousand years after it was formed. These bodies may have brought organics to the Earth's surface if they were traveling at a low velocity and thus were not pyrolyzed when the body on which they were carried hit the Earth's atmosphere.

Once the bulk of the planetesimals were ''swept up'' by the planets orbiting the Sun, the asteroids that orbited the Sun between Mars and Jupiter continued to serve as a source of meteorites. The asteroid belt exists because the gravitational perturbations of Jupiter are so great that it inhibits the coagulation of these smaller bodies into a planet. While the asteroids have defined orbits around the Sun, they tend to smash into each other–a process that results in their loss of dust and larger pieces with sufficient translational energy for these pieces to escape from their orbits and accelerate towards the Sun. Many of these bodies will impact with other planets, including the Earth, and bring organics to their surfaces. It is estimated that 80% of the original asteroid belt and an amount of material equivalent to a layer of material 0.2 to 1-km thick was deposited on the Earth as a result of these collisions. Accretion continues at a slower rate to this day with an estimated $30\,000 \pm 10\,000$ tons of dust per year reaching the Earth's surface.

Smaller meteorites survive impact with the Earth's atmosphere by the thermal ablation of their surface materials. This preserves the organics present below the surface of the meteorite from decomposing on impact with the atmosphere. These bodies may break into pieces when they hit the Earth's surface but the organics present are preserved. The much larger bodies survive the trip through the Earth's atmosphere but the impact is with such high energy that the body is almost totally pyrolyzed and the impacter gets so hot that any organics present are destroyed. The fate of each dust particle or larger body depends on its mass and velocity. Material originating from the asteroid belt usually has a lower velocity than those from comets and has a greater chance of survival. An impact on the atmosphere in Tunguska, Siberia (Russia) may have been due to cometary or meteorite material. The resultant shock wave blew down trees over a 2000 km^2 area.

Meteorites are our principal source of information about extraterrestrial material. Most meteorites do not contain much carbon but those that do, have as much as 2%. Analysis of the organic material present reveals that most of it is a polymeric matrix of organic material imbedded in an inorganic matrix. There is also a fraction of water-soluble organics, which accounts for less than 1% of the organic material present. This consists of diverse array of organics, many of which are reminiscent of biomolecules. These include

carboxylic and dicarboxylic acids amino acids, purines, pyrimidines, and simple sugar derivatives (Table 2).

There have been no direct analyses of comets although at the time of this writing there are several missions to comets are in progress. Spectroscopic analysis of the cometary coma, generated by the impact of the particles in the Sun's solar wind on the comet, revealed the presence of hydrocarbons and nitrile derivatives (Table 3). These findings give strong support to the hypothesis that comets contain reduced organics, some of which may have contributed to the inventory of organics on the Earth that led to the origins of life.

3.4 Hydrothermal Systems

Marine hydrothermal systems with their spectacular "black smokers," "white smokers," and unique ecosystems may have provided yet another environment in which the biomolecules required for the origins of life were formed. The internal heat of the Earth drives these vast systems of seawater circulating through the Earth's crust. Temperature ranges as high as 350 °C and pressures up to 20–30 mPa (200–300 bar) occur as this hot water percolates through potential mineral catalysts.

The thermal gradient between the magma at the tectonic spreading center and the 2 °C sea water drives the flow of water and its dissolved compounds down to the magma where they are reduced by the iron in the magma at the high pressures and temperatures there. The reduced metal ions are vented together with the sulfide formed by the reduction of sulfate. The highly insoluble metal sulfides generate black and, sometimes white, precipitates in the vicinity of the vent as soon as they encounter the cold ocean water. It is possible that reduced organics and ammonia are formed from more oxidized precursors by the magma. Laboratory studies have shown the reduction of molecular nitrogen to ammonia when it was heated to 500–700 °C and pressures of 0.1 Gpa. This reaction is inhibited by water and is most efficient with a 1 : 1 ratio of water and reductant. Nitrogen oxides (NO_2^-, NO_3^-) are readily reduced to ammonia by iron sulfide minerals and hematite at 500 °C. Thus, hydrothermal systems could have been the

source of ammonia required for the formation of nitrogen-containing organics on the primitive Earth. It is not clear whether the rate of ammonia production exceeded its rate of photolytic destruction by solar UV light.

More complex structures are unlikely to survive the high temperatures and pressures present directly in the vents but they may be formed from the reduced metal ions and sulfides generated by the vents. But organics may also have been formed away from the high temperature areas at the vents in which they would have been stable. The temperature gradient that drives the vent process also drives the circulation of sea through the reduced forms of metals and their sulfides deposited in the vicinity of the vent. This ''off axis'' circulation may bring oxidized compounds in contact with the reducing conditions and catalytic minerals leading to the formation of reduced organic and inorganic compounds. These ''off axis'' compounds would not come in contact with the hot magma and consequently would not be destroyed by the high temperatures.

There have been several recent findings of the formation of reduced organics from oxidized precursors using this hydrothermal model. The laboratory synthesis of some simple organics from carbon dioxide and carbon monoxide has been reported in simulations of hydrothermal reaction conditions. Iron, iron sulfides together with hydrogen sulfide reduced carbon dioxide to methane thiol (CH_3SH). The reduction of CO at 100 °C with a mixture of iron and nickel sulfides in the presence of methane thiol resulted in the synthesis of acetic acid and its methyl thioester (CH_3COSCH_3). Reactions of CO with iron sulfide at 250 °C and high pressures give low yields (0.07%) of pyruvate. Dipeptides are formed in the reactions of amino acids with CO, a mixture of CO and a mixture of iron and nickel sulfides, hydrogen sulfide, or methane thiol at 100 °C. These data suggest the possibility of forming simple peptides near hydrothermal vents but it appears unlikely that polypeptides of sufficient lengths to be catalysts could have formed by this route because they are hydrolyzed under similar reaction conditions.

4 Formation of Complex Structures

None of the compounds formed from the sources described in Sect. 3 are biopolymers of the type present in life as we know it. The concentrations of these reactants leading to biopolymers probably were so low that bimolecular reactions did not occur in the solution phase. Rather, it is thought that the reactions took place on mineral surfaces or in complexes with metal ions that selectively adsorbed and catalyzed the reactions of these organics.

If the molecules discussed in Sect. 3 are indeed the limit of complexity, then additional reactions had to have occurred to generate the biopolymers essential for the first life. Life is based on biopolymers or the self-organization of more complex structures as is observed in the formation vesicles from lipid molecules. The formation of more complex structures may have been driven by UV light, discharges, radioactivity, shock waves, and thermal processes on the early Earth. All of these energy sources also have the potential to degrade complex organics, so there may have existed a critical balance between the rates of formation and degradation of the molecules required for the first life.

4.1 Catalysis and Prebiotic Synthesis

It is likely that catalysis had a central role in the origins of life just as it has a central role in life today. For example, a complex array of structures and enzymes are required for the biosynthesis of proteins and nucleic acids. Certainly a much simpler synthesis of these biopolymers occurred on the primitive Earth, but it is highly likely that mineral and/or metal ion catalysis was involved. A catalyst is essential since it can carry out the following functions:

1. Selectively bind low concentrations of reactant molecules from a complex mix of organic structures present in an aqueous solution on the primitive Earth.
2. Enhance the rate of the reaction of the reactants so that they can form bonds faster than they would be degraded.
3. Selectively form a restricted number of reaction products so that not all possible isomers are formed. This is especially important in the formation of biopolymers in which if it is was desired to make one molecule of a polypeptide containing 100 amino acids of defined sequence by a random method, it would be necessary to synthesize 10^{130} molecules. If two identical molecules of a 40 mer of an RNA containing four different bases were required, it would be necessary to synthesize 10^{48} molecules.

Most of the studies of the origins of life do not consider the role of catalysis in prebiotic synthesis. Bernal first proposed in 1947 that mineral catalysis might have had a role in prebiotic synthesis. In the absence of life, minerals and metal ions were the most likely catalysts on the primitive Earth. For example, divalent metal ions were required in the synthesis of nucleosides from purines and ribose. The uranyl ion (UO_2^{2-}) and lead ion (Pb^{2+}) catalyzed the oligomerization of 5′-activated nucleotides. Mg^{2+} is usually an essential cation in the reactions resulting in the formation of the phosphodiester bond present in oligonucleotides. Montmorillonite clay has a central role in the formation of oligopeptides from aminoacyl adenylates (Sect. 8.1) and in the formation of oligonucleotides (Sect. 8.2). The minerals illite and hydroxylapatite catalyze the oligomerization of negatively charged amino acids (Sect. 8.1). Hydrotalcite catalyzes the oligomerization of glycolaldehyde phosphate to the dimer erythrose-2,4-diphosphate as the major reaction product. Additional examples of catalysis are discussed in Sect. 8.

The current scenario for the origins of life proposes a series of chemical reactions yielding first simple products, then more complicated compounds. The reaction conditions for each stage of the process may very well have been quite different, and they probably required different catalysts. The chemical evolutionary process may have paralleled the changing reaction conditions on the primitive Earth that resulted from its cooling and the diminished flux of impacting comets and meteorites. The host of variables in the possible reaction conditions makes it almost impossible to define the precise conditions under which life originated on the early Earth.

5 Formation of Nucleic Acid Bases, Nucleosides, and Nucleotides

The central biopolymers of life today are proteins, DNA, and RNA. Amino acids, the building blocks of protein, are

found in meteorites, and formed directly in many prebiotic simulation reactions. The monomers for DNA and RNA are not found either in meteorites or in simulation experiments, so if they were present on the primitive Earth, they should have been synthesized by reactions that occurred here.

The prebiotic synthesis of RNA will be emphasized in this review. Proteins will only be discussed briefly because their ability to store information has not been established. If primitive life did not have the ability to maintain the information that led to its formation, it would not have evolved.

Many scientists in this field feel that RNA monomers are too complex to have formed spontaneously on the primitive Earth. They propose that simpler precursors to RNA formed first which directed the synthesis of RNA. While possible pre-RNAs have been proposed, no prebiotic synthesis of these pre-RNAs has been demonstrated (Sect. 8.4). In addition, unless the pre-RNAs were able to direct the synthesis of RNA monomers, the problem of formation of the RNA monomers still remained if the transition of pre-RNAs to RNAs took place using the pre-RNAs as templates. Consequently, the formation of RNA monomers and their polymerization will be emphasized.

5.1 Nucleic Acid Bases

Nucleic acid bases have been found in the Murchison meteorite, which fell in Murchison Australia in 1969, and other meteorites containing carbon compounds. Condensation reactions of HCN are another source of purine and pyrimidine bases. The condensation of HCN proceeds in a stepwise fashion in aqueous solution and generates a tetramer, diaminomaleonitrile (DAMN). Further reaction of DAMN with HCN generates a mixture of low molecular weight oligomers. Hydrolytic decomposition of the oligomer yields adenine, guanine, orotic acid, uracil, 4,5-dihydroxypyrimidine, and 5-hydroxyuracil. More recent studies with a solution of ammonium cyanide left at $-78\,^{\circ}C$ for 27 years generated a polymer, which on hydrolysis, resulted in the formation of adenine, guanine, hypoxanthine, xanthine, 2,6-diaminopurine, uracil, 5-aminouracil, 5-hydroxyuracil, orotic acid, 5-aminoorotic acid, and 4,5-dihydroxypyrimidine (Fig. 1).

Alternatively, photolysis of DAMN generates 4-aminoimidazole-5-carbonitrile (AICN). Reaction of AICN or its corresponding amide (AICA) with simple nitrile derivatives results in the formation of an array of purine bases including adenine, guanine, diaminopurine, hypoxanthine, and xanthine. The pyrimidines cytosine, uracil, and diaminopyrimidine are formed by addition reactions to cyanoacetylene. Heating formamide to $160\,^{\circ}C$ in the presence of mineral catalysts also forms adenine and cytosine.

Acid hydrolysis of the Murchison meteorite, which has 2–3% carbon, results in the release of adenine, hypoxanthine, guanine, xanthine, and uracil. The yields are low but there is the potential of delivery of substantial amounts of these compounds on the Earth from dust and meteorites that get broken off the asteroids (Sect. 3.3).

5.2 Nucleosides

There are two problems associated with the prebiotic synthesis of nucleosides. One is

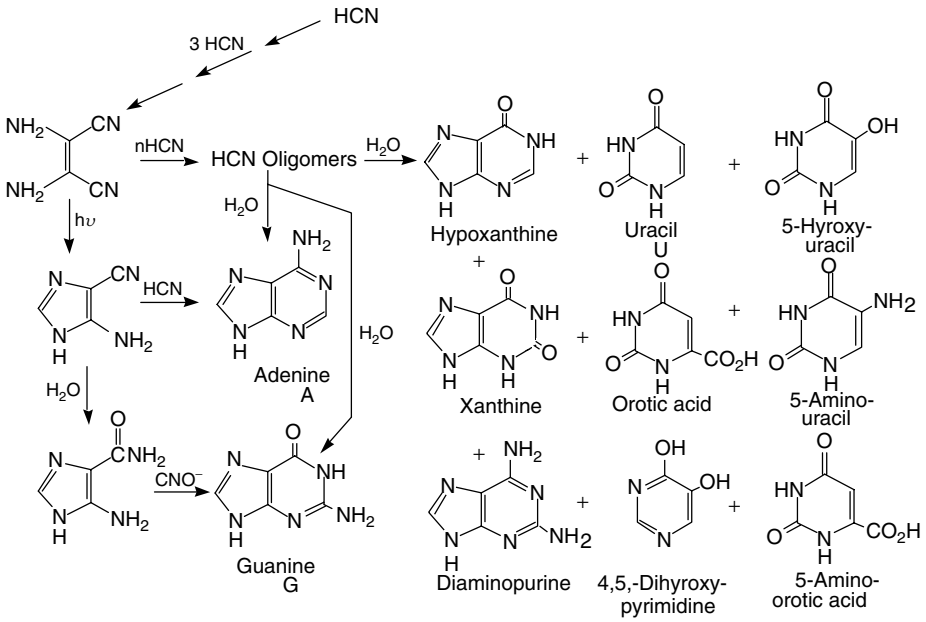

Fig. 1 Formation of purine and pyrimidine bases from HCN.

the formation of ribose and the second is the formation of nucleosides by the reaction of ribose and with a purine or pyrimidine base.

5.2.1 **Prebiotic Synthesis of Ribose**

Several routes have been proposed for prebiotic ribose synthesis. The first was based on the Formose reaction, the condensation of formaldehyde in basic solution catalyzed by divalent metal ions. This reaction, however, produces an array of more than 35 sugars, most in low yield. It is not clear how the small amount of ribose in this complex mixture was selected from all the other sugars present to form nucleosides.

Two improvements of this synthesis have been reported. One is the use of a magnesium ion–lead ion mixture that catalyzes the formation of all four pentoses in roughly equal amounts with little or no formation of any other sugars. This catalytic mixture decreases the number of products formed from over 20 to four. Interestingly, incubation of any one of these pentoses with the magnesium–lead catalyst results in its being converted to equal amounts of the four pentoses. In addition, these pentoses are formed by incubation of hexoses with the magnesium–lead catalyst.

A promising synthesis of ribose is from the reaction of formaldehyde with calcium hydroxide in the presence of borate. The calcium catalyzes the synthesis of sugars via the Formose reaction while the borate forms a complex with the hydroxyl groups of the ribose and ribose precursors that prevents its conversion to hexoses and higher molecular weight sugars as well as inhibiting the formation of brown decomposition products.

Ribose may also be produced by the reaction of glycolaldehyde phosphate with

formaldehyde (Fig. 2). Further reaction of glyceraldehyde phosphate with glycolaldehyde results in ribose-2,4-diphosphate. The overall yield is 33% in a one-pot reaction starting from glycolaldehyde phosphate and formaldehyde. The main problem with this scenario is the absence of a convincing prebiotic route to glycolaldehyde phosphate. Glycolaldehyde can be converted to glycolaldehyde phosphate by reaction with amidotriphosphate (NH_2Pi_3).

The Murchison meteorite contains sugar derivatives in which the aldehyde group of the sugar is either oxidized to an acid or reduced to an alcohol. One speculative route to these products is the formation of ribose in the asteroid and the subsequent oxidation and reduction of the ribose in the meteorite or its parent asteroid. If this speculation is correct, there may be meteorites in which this oxidation did not occur.

5.2.2 Prebiotic Synthesis of Nucleosides from Ribose and Bases

There has been limited success in the formation of nucleosides by the reaction of purine and pyrimidine bases with ribose. The dry-phase reaction of purines and ribose at 100 °C in the presence of Mg^{2+} or Ca^{2+} results in low yields of the natural β-anomers of the nucleotides (Table 4). No nucleosides were detected in comparable reactions using pyrimidine bases. This is one of the reasons cited for suggesting that compounds with simpler structures were the building blocks for the first genetic material. So far, it has not been possible to find a building block simpler than the RNA monomer that is formed by a plausible prebiotic reaction (Sect. 9).

5.3 Nucleotides

The addition of the phosphate grouping to nucleosides proceeds efficiently in the absence of water at 100 °C in the presence of urea and ammonium phosphate. The phosphorylation of uridine (Fig. 3) yields a mixture of nucleotides including 43% of 5′-UMP. The problem here is that a rather specific combination of reagents ($NH_4H_2PO_4$ and urea) is required for this phosphorylation to take place. Other

phosphate salts are much less effective in generating nucleotides from nucleosides.

Activated phosphates with pyrophosphate bonds may have been prepared by the reaction of 5′-nucleotides with trimetaphosphate (Fig. 4). The initial product is a tetraphosphate, which is hydrolyzed to the corresponding triphosphate. It is not clear whether 5′-nucleoside triphosphates were important in the first life or were the products of more sophisticated metabolic pathways that developed after life had evolved.

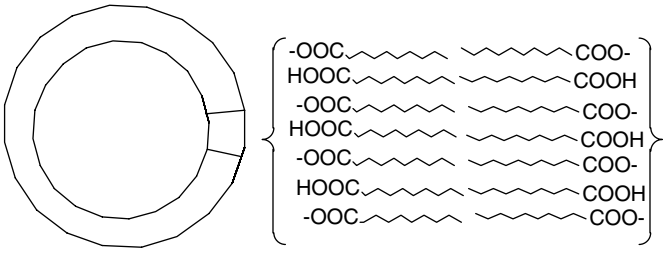
6 Membranes and Vesicles

Most scenarios for the first life propose the presence of an interacting group of biological polymers that is separated from the surrounding environment by a semipermeable membrane. The membrane is required to keep the interacting polymers and their metabolites in close proximity and to protect them from a hostile external environment. The membrane used in contemporary cells is made up of

phospholipids, but there are no convincing prebiotic syntheses of these materials. Linear fatty acids containing a minimum of 10–12 carbon atoms will form stable spherical vesicles. Here the pH is adjusted so that half the acids are in their anionic carboxylate form and the others are present as the acids (Fig. 5). Hydrogen bonding between the carboxylate and acid groups stabilizes these vesicles. Branched-chain fatty acids and hydrocarbons are formed in electric discharge reactions of methane and water. It is unlikely that branched acids would associate closely enough in a phospholipid to form a stable bilayer.

Linear carboxylic acids are formed in the reaction of carbon monoxide with iron at high temperatures and pressures under conditions reminiscent of those present in hydrothermal systems (Sect. 3.4). In studies on the formation of vesicles from linear carboxylic acids, it was observed that montmorillonite clay catalyzes vesicle formation. This is the same montmorillonite that catalyzes the formation of RNA from activated RNA monomers (Sect. 8.2). The vesicles formed catalytically trap some of the montmorillonite on the inside of the vesicles. When RNA is bound to the montmorillonite, it still catalyzes the formation of vesicles; a finding that suggests that this may have been a way of placing a catalytic system within a vesicle that has the capability of generating genetic material in a cell-like structure. It has not been determined at the time of writing whether it is possible to form RNA inside the vesicle by montmorillonite catalysis.

The compounds in the liquid phase within the vesicle are protected from dilution and interaction with reactive organic compounds in the environment. The problem is that the nutrients essential for life may not be able to diffuse into the vesicle and waste material may not be able to diffuse out. Vesicles formed from phospholipids containing carboxylic acids with ten carbon atoms are "leaky" in that they let materials go inside but they will also let them go outside as well. Vesicles containing phospholipids with 14 carbons are more selective in that they allow small compounds to pass through the cell wall but do not allow the polymers. For example, it was shown that vesicles containing phospholipids with 14 carbon atoms with encapsulated enzyme polynucleotide phosphorylase (PNPase) allowed the passage of adenosine diphosphate (ADP) into the vesicle and the PNPase catalyzed the conversion of ADP to oligomers of A. At the same time, the vesicles prevented the diffusion of a proteases enzyme through the bilayer that would destroy the PNPase. This experiment suggests that, if it were



(a) Vesicle cross-section (b) Section of vesicle wall

Fig. 5 Schematic diagram of a vesicle.

possible for activated RNA monomers to diffuse through a vesicle, it would be possible to generate RNAs by clay mineral catalysis, which would either remain bound to the encapsulated montmorillonite or be too big to escape though the leaks in the vesicle.

7 Chirality

The molecules present in living systems consist of one of the two possible mirror-image forms called *enantiomers*. L-amino acids and D-nucleotides are the basic building blocks of proteins and nucleic acids respectively in contemporary life. The mirror-image D-amino acids and L-nucleotides occur rarely in contemporary life.

It is not known how the enantiomers observed in living systems were selected initially. The *frozen accident* theory proposes that a chance event resulted in the survival of the life bearing L-amino acids and D-nucleotides, and these amino acids and nucleotides have been associated with life ever since. The frozen accident theory assumes that life consisting of D-amino acids and L-nucleotides also existed at one time, and this chance event (a mutation?) resulted in the demise of this life form or the accelerated growth of the other. Scientists have been searching for an environmental explanation of the observed handedness that has investigated possible chiral forces as the source of the configuration of the amino acids and nucleotides of life. To date, there are no convincing experiments or explanations relating to this observation, and the origin of chirality remains an open question.

Initially it was believed that all the amino acids extracted from the Murchison meteorite contained equal amounts of both the D-, and L-enantiomers. The D- or L-enantiomers of amino acids interconvert very slowly (Fig. 6a). This interconversion is very small over time scale of hundreds of years but it is appreciable over thousands of years. So it was not surprising that a mixture of equal amounts of both D- and L-enantiomers were found in the Murchison meteorite that contains materials over 4 billion years old. Later, it was observed that some of the nonbiological amino acids in Murchison contained small excesses of the L-enantiomers. The particular amino acids had two substituents attached to the carbon atom bearing the amino and carboxyl groups (Fig. 6b, R and CH_3). This substitution would greatly inhibit the loss of their L-configuration for a time much longer than would a regular biological amino acid.

One of these amino acids, L-isovaline (Fig. 6b) catalyzes condensation of glycolaldehyde to form an excess of the D-tetrose, threose. Thus, it is possible that amino acids with an additional substituent at the carbon bearing the amino and carboxyl groups initiated the formation of

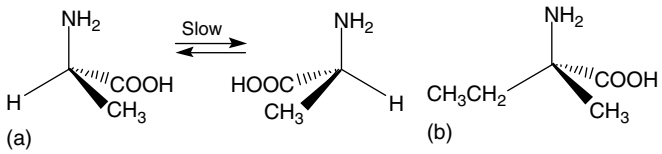


Fig. 6 (a) D-, L-enantiomers of alanine and (b) Isovaline, an amino acid that does not racemize.

D-sugars, the handedness of the sugar moiety in nucleic acids.

The observation of circularly polarized light in an area of star formation suggested that this might be the type of environment in which chiral selection occurred. Circularly polarized light can be either right- or left-handed. Laboratory studies have demonstrated that circularly polarized light will preferentially destroy one of the enantiomers in a D-, L-mixture faster than the other, thus leaving behind an excess of one of the enantiomers. This finding provides a possible explanation for the observation of an excess of one of the amino acid enantiomers in the Murchison meteorite. Since many of the theories and experiments to explain the origins of chirality put forth in the past 50 years have been shown to be incorrect, there is a reasonable chance that this proposal will not stand the test of time either.

In another approach to this problem, it was demonstrated that the montmorillonite catalysis of the reactions of D, L-activated mononucleotides generates more homochiral than heterochiral oligomers. This is not a claim of chiral selectivity. It does suggest the possibility of formation of oligomers composed mainly of the same but opposite handedness. This could have resulted in the formation of two different forms of life with opposite handednesses in their biopolymers. If this were the case, then it is assumed that a chance event led to one form predominating over the other.

8
Prebiotic Formation of Biopolymers

The interactions of biopolymers with themselves and with small molecules are an essential part of the biochemistry of living systems. The research outlined in Sect. 3 has uncovered potential prebiotic routes to monomers that may have been precursors to proteins and nucleic acids. Although it has not been possible to propose plausible, detailed chemical routes to all the necessary monomers, the findings suggest a number of possible pathways by which some of them may have formed on the primitive Earth. Since the question of the prebiotic formation of monomers has been solved in principle, if not in practice, there has been a shift in research focus to the problem of the prebiotic formation of biopolymers.

It is likely that on the primitive Earth, biopolymers formed in the presence of water, the principal liquid present. It is not possible to link amino acids to polypeptides or mononucleotides to nucleic acids in the presence of water. Additional energy in the form of activating groups or condensing agents is required. The activated monomers tend to hydrolyze in the presence of water, so the continuous formation of the high-energy compounds would have been essential for the formation of polypeptides and nucleic acids. An alternative scenario is for the polymerization to have occurred in the absence of water but that probably required an alternating wet and dry environment.

8.1
Polypeptides

Amino acids are formed in prebiotic simulation reactions and are found in carbonaceous meteorites, so it is reasonable to believe that they were present on the primitive Earth. Since polypeptides are not genetic (information storing) molecules, they may not have played a central role

in the first life because they are unable to reproduce themselves. There is the possibility that mineral or metal ion catalysts directed the continuous formation of polypeptides that in turn catalyzed the synthesis and/or replication of genetic polymers. If the mineral catalysts had sufficient selectivity, this could have resulted in the continuous formation of the same catalytic polypeptides.

Initial studies on prebiotic polymerization focused on the formation of polypeptides from amino acids. Most of these early studies invoked the use of heat to drive the polymerization, and anhydrous reaction conditions were used. The product mixtures from these reactions contain thermal polymers with molecular weights as high as 4000. Amide (peptide) and other bonds linked these amino acids together. The materials were shown to possess some weak catalytic activity.

Another synthesis of polypeptides involves the condensation of aminoacyl adenylates on montmorillonite to form the polypeptide adducts of 5′-adenylic acid (Fig. 7). This reaction proceeds in aqueous solution to form oligomers of up to 40 amino acids in length. Although it is difficult to envisage the formation of appreciable amounts of such a high-energy acyl anhydride in the presence of water, the experiment does suggest that other less reactive amino acid derivatives may condense to polypeptides on mineral surfaces.

Polypeptides are formed in aqueous bicarbonate buffer by the action of *N*′,*N*′-carbonyldiimidazole (CDI) on amino acids. The reaction proceeds via the carboxyanhydride (Fig. 8) to give an 8 to 10 mer, which precipitates from solution. Since CDI is unstable in water, it should have been produced continually on the primitive Earth. These studies do show that condensing agents capable of generating *N*-carboxyanhydrides may have initiated the formation of polypeptides on the primitive Earth.

Reaction of glutamic acid with *N*′,*N*′-carbonyldiimidazole is catalyzed by the clay mineral illite. Oligomers greater than 50 mers in length were obtained in a feeding reaction where a mixture of glutamate and CDI were added 50 times to the illite. Aspartic acid, another negatively charged amino acid, also formed polymers when a carbodiimide was used as the condensing agent and hydroxylapatite was the mineral surface on which the reaction took place.

8.2 Polynucleotides

The polymerization of mononucleotides to polynucleotides under plausible prebiotic

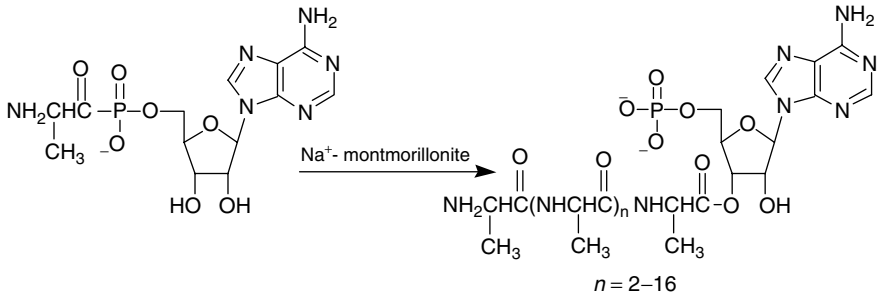

Fig. 7 Polymerization of aminoacyl adenylates on montmorillonite.

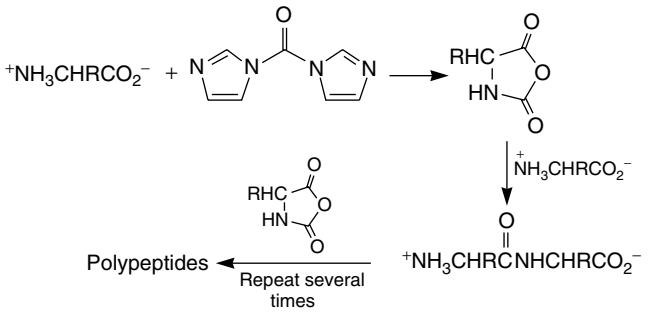

Fig. 8 Polypeptide formation in water using *N*′,*N*′-carbonyl diimidazole carbonyl as the condensing agent.

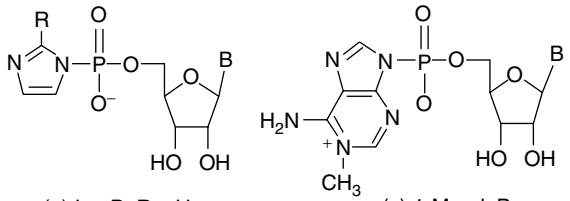

Fig. 9 Activated RNA mononucleotides.

conditions has been reported. Initial studies in which the 2′,3′-cyclic phosphates of nucleotides were heated under anhydrous conditions in the presence of ethylenediamine resulted in the formation of polymers containing up to 13 monomer units (a 13 mer). This synthesis is inhibited by water, hence could have proceeded only in dry areas on the primitive Earth. In addition, there have been no prebiotic syntheses of the requisite diamines.

The oligomerization of the nucleoside 5′-phosphorimidazolides (5′-ImpN) (Fig. 9a) proceeds in aqueous solution in the presence of catalysts. Oligomers as long as the hexamers linked by 2′,5′-phosphodiester bonds were observed in reactions of 5′-ImpN in aqueous buffer catalyzed by Pb^{2+}. A major synthetic advance was made using uranyl ion (UO_2^{2+}) as the catalyst. 2′,5′-linked oligomers of adenylic acid as long as the hexadecamer were formed at room temperature in water. The reaction has been extended to the synthesis of oligomers of cytidylic and uridylic acid.

Syntheses of mainly 3′,5′-linked oligomers were observed in the reaction of the 5′-phosphorimidazolide of adenosine (Fig. 9a, B = adenine) in aqueous solution in the presence of the clay mineral montmorillonite. Oligomers as long as 10 mers were obtained which have a 2:1 ratio of 3′,5′ to 2′,5′ links. The oligomers formed in this reaction also contain some $A^{5'}$ppA groupings. Cyclic dimers are also formed. This reaction has also been extended to cytidylic and uridylic acids. The proportion of 2′,5′-linkages is greater with oligo(C)s and oligo(U)s than it is for oligo(A)s. The

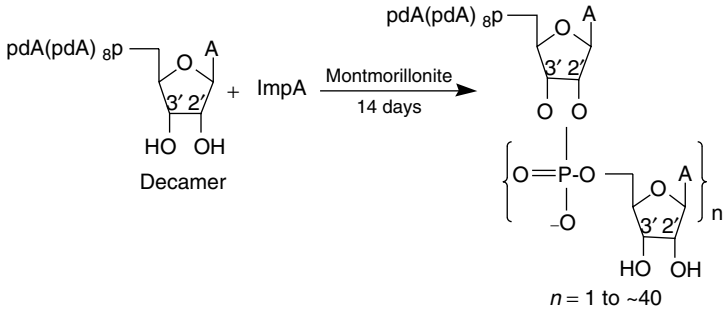

Fig. 10 Elongation reaction in which ImpA is added daily to a decameric oligomer.

oligo(C)s formed by the reaction of the 5′-phosphorimidazolide of cytidine (Fig. 9a, B = cytosine) on montmorillonite serve as templates for the formation of oligo(G)s (Sect. 9.2) showing that these short RNAs are capable of storing genetic information.

The RNA oligomers formed in these reactions were not long enough to initiate the processes of replication and catalysis expected in simple living systems, but this research constituted the first step in that direction. The next stage of this montmorillonite-catalyzed synthesis was the observation that it was possible to make RNA oligomers as long as 50 mers in a ''feeding'' reaction. In this approach, an activated monomer was added daily for 14 days to a decameric primer bound to the montmorillonite (Fig. 10). The decamer elongated to a 40 to 50 mer in the two-week time period.

The current status of this synthesis is the formation of 40–50 mers in one day using a 1-methyladenine activating group (Fig. 9c) in place of imidazole (Fig. 11). The advantage of this synthesis is that it provides a facile route to these longer oligomers so that they can be tested for their ability to bind and catalyze reactions; a property consistent with the proposed RNA world.

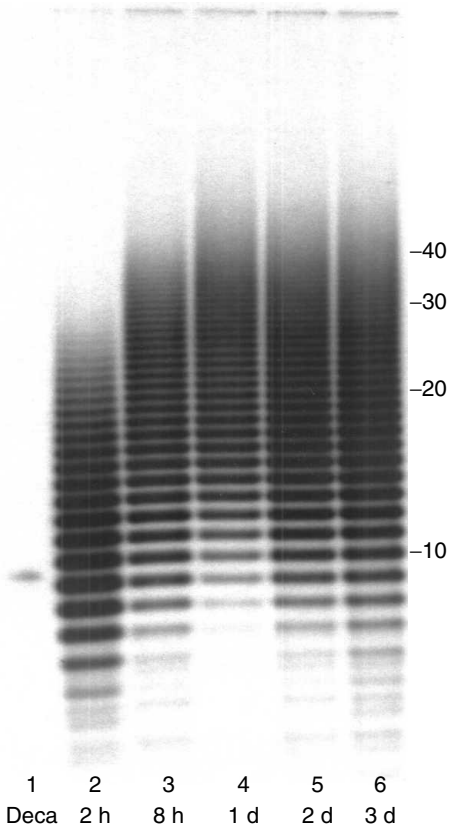

Fig. 11 Formation with time of oligomers formed from MeadpU (Figure 9c) on montmorillonite. Lane 1 10 mer marker; lanes 2, 3 h; 4, 8 h; 5, 1 day; 6, 2 days with additional MeadpA added; 7, 3 days with 2 additions of MeadpA added.

8.3 Selectivity in Catalyzed Reactions

Montmorillonite, like most catalysts, accomplishes the observed catalytic effect by lowering the activation energy of specific reaction pathways. Since the catalyst does not lower the activation energy of all reaction pathways, it produces a limited number of isomers of the products formed. It was recognized early in the studies on prebiotic synthesis that it would be difficult to form long polymers of amino acids or nucleotides because of the large number of possible isomers that would be formed in the random synthesis. Studies on the uncatalyzed synthesis of RNA oligomers from one-molar solutions of the imidazole-activated monomers (Fig. 9) yielded mainly dimers accompanied by trace amounts of higher molecular weight products. The successful synthesis of 40 mers using only a few milligrams of starting material and a montmorillonite catalyst clearly shows that the montmorillonite is generating a limited number of isomers. This was confirmed in a separate study of the formation dimers to pentamers using activated monomers of A and C. It was determined that in the pentamer fraction, there were four main products produced in yields of 4.3–13% while a random synthesis would have generated 512 products in 0.2% yield for each. Thus, catalysis solves the problem of producing too many isomers so that it is possible to make long oligomers.

8.4 PNA as a Precursor to RNA

The RNA world postulate suggests that RNA was the most important biopolymer in the first life on Earth. The RNA world is a generally accepted concept because it has been demonstrated that RNA has catalytic activity as well as the ability to store genetic information. The problem many scientists have with this scenario is that it assumes that RNA formed from RNA monomers that were formed by prebiotic processes on the primitive Earth. It has been noted previously that the complexity of the RNA structure and the failure, to date, to discover a plausible prebiotic pathway to RNA monomers has resulted in the search for alternative genetic molecules that have the potential for evolving into an RNA.

One of the frequently cited alternatives to RNA is peptide nucleic acid (PNA) (Fig. 12). The advantages of this structure are that it has no chiral centers and the distance between the bases is comparable to those in DNA and RNA. These factors make it possible for PNA to form double helical complexes with either D- and L-DNA or RNA. In addition, it is possible for PNA to serve as a template for the formation of RNA demonstrating that the transition from life based on PNA to RNA

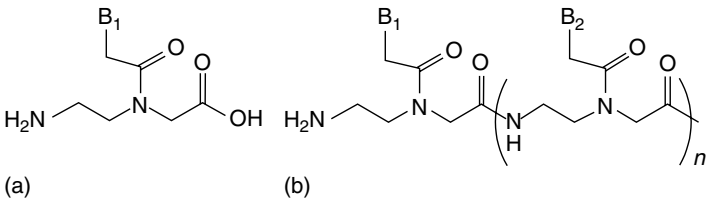

Fig. 12 PNA (a) monomer and (b) polymer.

life was possible if the synthesis of the RNA monomers had been accomplished.

There are major problems with PNA as a precursor to RNA. So far, there is no reported prebiotic synthesis of PNA monomers or polymers, and it degrades spontaneously in water. It appears unlikely that it will be possible to form polymers of PNA starting from the monomer because of competing cyclization reactions and RNA monomers are needed for the transition from PNA to RNA. The latter problem is the same complaint concerning the prebiotic synthesis of RNA so it will have to be assumed that a biosynthesis of RNA monomers occurred during the PNA world before the RNA world arose.

9
Polymer Reactions

The ultimate goal of research into the origins of life is the formation of polymers that replicate and catalyze enough reactions to maintain the viability of the reaction system that generated the first life. In the RNA world scenario, oligomers catalyze their own replication and their formation from simpler precursors in the absence of proteins. The replication process provides the means of information storage, which is not possible with proteins. The discovery of the limited catalytic action of RNA suggests that protein catalysis (enzymes) is not required. The absence of a requirement for protein makes the postulated RNA world much simpler than one requiring the concurrent prebiotic synthesis of both DNA and protein.

9.1
Ribozymes

Ribozymes, the RNAs that catalyze chemical reactions, are central to a scenario for primitive life on Earth based solely on RNA. The possible role of ribozymes in the RNA world was demonstrated by the catalytic elongation of a pentamer of cytidylic acid to a series of oligomers as long as the 30 mer by a ribozyme obtained from the protozoan Tetrahymena. This experimental finding suggests that oligomers produced in prebiotic processes described in Sect. 8.2 may have been elongated by the ribozymes of the RNA world. In addition, over twenty ribozymes that catalyze the reactions of biomolecules as well as structures that have no known connection with biological systems are known.

9.2
Template-directed Synthesis

The non-enzymatic template-directed synthesis of complementary RNA chains would have been an important process of information storage and RNA proliferation in the proposed RNA world. The synthesis of oligo(G)s (oligomers of guanylic acid) proceeds very efficiently on poly(C) templates with 2-methylImpG (Fig. 9, R $-$ CH_3, base $=$ G) as the starting material. The reaction occurs because the hydrogen bonding and stacking interactions of the guanine bases on the poly(C) template orient the monomer units for reaction. Oligo(A)s is formed less effectively in the reaction of ImpA on poly(U). One explanation for the low efficiency of oligo(A) formation is the weaker hydrogen-bonding interaction between A and U. No oligomers are formed in the reactions of the phosphorimidazolides of pyrimidine nucleosides on purine templates.

The failure of the pyrimidine nucleotide reactions is attributed to the virtual absence of stacking interactions between the pyrimidine nucleotide monomers bound to the poly-purine nucleotide chain. The

absence of the proximate association of pyrimidine monomers on the template means the monomers do not react to form phosphodiester links between the pyrimidine nucleotides. The failure to replicate pyrimidine monomers is also believed to explain why copolymers, containing equal amounts of purine and pyrimidine nucleotides, do not serve as templates for RNA synthesis. So far, the failure to discover conditions for the template-directed synthesis of oligomers containing both purine and pyrimidine bases is a major deficiency in the theory of the RNA world scenario.

10
Catalysis and the Origin of Life

Catalysis by substances such as minerals and metal ions on the primitive Earth was essential for the initiation of the first life on Earth. Studies have demonstrated that a clay mineral will catalyze the synthesis of an RNA containing up to 40 to 50 monomer units. The same activated monomers yield oligomers containing only two or three monomers units in the absence of the catalyst. The RNAs that form have a limited number of sequences and not all possible isomers are formed. This suggests that catalysis could result in the continual generation of an ensemble of the same structures that could have served as the starting point for the origins of life. It has been recently shown that the same montmorillonite that catalyzes the formation of RNA also catalyzes vesicle formation. Some of this catalyst with bound RNA is also encapsulated in the vesicle. This finding suggests that a few key catalysts may be all that was needed for the origin of life to occur. The search for catalysts that may have catalyzed the reactions of potential biomolecules on the primitive Earth should be emphasized in future studies on the origins of life.

Keywords

Action Potential
A brief reversal of the neuronal membrane potential (i.e. a *depolarization*) that propagates along the nerve fiber. The universal currency by which neurons communicate over long distances.

Adaptation
The tendency for the effect of a stimulus on a sensory receptor to diminish with time. Adaptation means that a sensory receptor can function over a wide range of stimulus intensities without saturating.

Afferent Nerve
Nerve fiber that conveys sensory information to the central nervous system (i.e. which *affects* the behavior of the organism).

Depolarization
The normal negative resting potential of a neuron becomes more positive following a net influx of positive charge across the cell membrane.

Efferent Nerve Fiber
Nerve fiber that conveys a command to the muscles of an animal (i.e. which *effects* a motor action).

Hyperalgesia
A heightened pain state.

Ion Channel
Membrane protein with a central pore, which conducts ions across the cell membrane. The pore is usually selective for particular ions, for example Na^+ ions, which, because they are more concentrated outside the cell, will flow in and *depolarize* the cell membrane potential (i.e. make it more positive).

Neuropathic Pain
Long-lasting pain caused by nerve injury.

Nociceptor
A primary sensory neuron that is activated by painful stimuli (i.e. a receptor for noxious stimuli).

Primary Sensory Neuron
A neuron which directly detects sensory stimuli – examples include receptors for touch, pain (nociceptors), and light (photoreceptors).

Sensitization
The opposite of adaptation: the effect of a stimulus on a primary sensory neuron increases with time. Sensitization is a property only seen in nociceptors.

Transduction
The conversion of a sensory stimulus into an electrical signal in a sensory neuron.

The sensation of pain informs us that potentially or actually damaging stimuli (noxious stimuli) are impinging on our bodies. All animals, and even many single-celled organisms that could scarcely be dignified by the name animal, show some form of avoidance reaction in response to noxious stimuli. Pain has therefore been a feature of many forms of life since early in evolution, and we would expect pain to be a highly evolved and complex sensation, responsive to a multitude of harmful stimuli, either those present in the external environment or those generated within the organism itself.

The word ''pain'' causes some difficulties because it covers a multitude of quite separate concepts. Pain refers to the processes involved in detection of the physical effects of an injury (e.g. the pain of a fracture); to the perceptual and emotional reaction to an injury (the ''feeling'' of pain); and to similar sensations experienced in response to a purely emotional event (e.g. the pain of parting). Sherrington, in 1906, removed the emotional connotations of the word ''pain'' from the physical process of detection of a painful stimulus by coining the word ''nociceptor'' (a receptor for noxious stimuli) to refer to those primary sensory neurons that are activated by stimuli that we would regard as painful. The existence of nociceptors as a separate class of sensory neurons was doubted for many years, and it was proposed instead that the sensation of pain could result from the strong stimulation of sensory receptors responsible for detecting nonpainful stimuli, an idea which was given support by the discovery of second-order neurons in the deeper layers of the dorsal horn of the spinal cord which respond to a wide range of stimuli, both nonnoxious and noxious. However, Ed Perl in 1969 recorded directly from primary afferent nerve fibers and was able to demonstrate clearly that a separate class of primary sensory afferents responding only to high-threshold stimulation did indeed exist and had properties quite distinct from those of receptors responding to nonnoxious stimulation. Thus, the existence of a distinct class of nociceptive neurons, as postulated by Sherrington, was finally confirmed.

Nociceptors, like all somatic sensory neurons, are ''long'' neurons in which the sensory terminal must be depolarized and action potentials elicited in order to communicate to the distant central synaptic terminals. The generator current activated in nociceptive nerve terminals by all noxious stimuli must therefore be

inward, as it is in all somatic sensory neurons. In many other respects, however, nociceptive neurons differ from other sensory neurons, although most of the functional differences are readily explicable in terms of the tasks that nociceptors are designed to carry out. Most obviously, a painful stimulus is, almost by definition, large in magnitude, so the cellular amplification pathways that form a prominent part of (for instance) olfactory and visual sensory transduction are not often seen in nociceptive transduction – most stimuli, in fact, act directly to gate an ion channel. Our current understanding of ion channels important in nociception is discussed below. Secondly, while most sensory receptors respond with exquisite sensitivity to only a single sensory modality (for instance, a narrow band of wavelengths of light in the case of visual receptors), nociceptors are typically polymodal, responding to a wide range of stimuli, which may include strong mechanical stimuli, heat, extreme cold, and a range of noxious chemical stimuli. Polymodal behavior makes sense in the context of pain, where the organism will be more concerned with detecting a noxious stimulus and taking appropriate avoiding action, rather than with analyzing the precise nature of the stimulus. Finally, in all other sensory receptors, adaptation is seen in response to the maintained presentation of a stimulus, a property that enables the receptors to operate over a wide range of stimulus intensities. The response of nociceptors, in contrast, typically increases, or sensitizes, in response to a prolonged or intense stimulus, a property that ensures that a noxious stimulus is not ignored by the organism. Our current understanding of the molecular basis of sensitization is discussed below.

1
Ion Channels Gated by Noxious Stimuli

1.1
Ion Channels Gated by Noxious Heat

Many nociceptors, both unmyelinated and myelinated, respond to elevated temperatures with an action potential frequency that increases exponentially as the temperature increases above ca. 45 °C, which corresponds closely to the temperature at which a human observer would report a transition of the quality of the sensation from pleasant warmth to mild heat pain. An inward membrane current with similar properties was first recorded in our lab from isolated primary sensory neurons. The heat-sensitive neurons are small sensory neurons, as expected for nociceptors. The ion channel through which the current passes is activated at temperatures above 45 °C, turns on with a delay of ca. 35 ms following a temperature change, and is highly permeable to calcium and to monovalent cations. There is also a second neuronal population with a higher heat threshold of around 51 °C.

The heat-sensitive ion channel now thought to be responsible for the 45 °C threshold heat response was cloned in 1997 by the group of David Julius, by an expression cloning strategy using responsiveness to capsaicin, the active extract of chili peppers, as a probe. The 6-transmembrane (6-TM) channel that was obtained is a member of the TRP channel family, now named TRPV1 (VR1 originally). The channel passes an inward

current in response to temperatures above 45 °C, and is also activated by low pH. The sites of binding of capsaicin (to the intracellular loop between transmembrane domains 2 and 3) and protons (extracellular, adjacent to the channel mouth) have now been identified, but the molecular rearrangements involved in the gating of the channel by heat remain mysterious. In most aspects so far investigated, the properties of TRPV1 correspond closely to those seen in the corresponding population of nociceptive neurons (i.e. those with a heat threshold at ca. 45 °C). A second heat-sensitive channel named TRPV2 (VRL1 originally), showing substantial homology to TRPV1, was subsequently cloned. This channel is capsaicin-insensitive and has a higher heat threshold, and seems likely to be the channel expressed in the high-threshold population of nociceptors mentioned above.

Mice in which TRPV1 has been deleted are still sensitive to noxious heat, albeit at a slightly higher temperature. The explanation may be that they sense heat using TRPV2, but it is possible that other as-yet undiscovered noxious heat sensors also contribute. The most obvious defect in the TRPV1$^{-/-}$ mice was that the heat hyperalgesia observed following inflammation was almost completely abolished (discussed further below).

1.2 Ion Channels Gated by Noxious Cold

Most nociceptors respond to noxious cold temperatures (below around 20 °C), but not to innocuous cold. The ion channel likely to be responsible was identified by searching the human genome database for channels containing a 6TM motif plus the N-terminal domain ankyrin repeat characteristic of TRP channels. ANKTM1 (more recently renamed TRPA1) is activated by cooling below 17 °C, but is not activated by menthol, which potently activates TRPM8, the channel responsible for the sensation of non-noxious coolness. ANKTM1 is expressed in a subset of the neurons which also express TRPV1, the receptor for noxious heat, which may explain why noxious cold is described as ''burning.''

1.3 Ion Channels Gated by Acid

The first acid-sensing ion channel (ASIC, now called ASIC1) was cloned in a search for additional members of the amiloride-sensitive ion channel family, which includes a number of epithelial sodium channels. ASIC1 generates a transient inward current in response to even mild acidification, and is expressed in sensory neurons, suggesting a role in signaling the acidification associated with anoxia and metabolic overload. The main difficulty with this idea is the extremely transient nature of the ASIC1 response, and the powerful adaptation to even mild acidification, which makes a role in sustained signaling of acidotic pain seem improbable. ASIC1 is also widely expressed in neurons of the CNS, where its function is unknown. A second member of the same family, BNC1, is now recognized as acid-sensitive and has been renamed ASIC2. Like ASIC1, it is widely expressed in neurons, including small sensory neurons, but it generates a more sustained inward current in response to acidification, which may make it a more promising candidate for a physiological sensor of the pain associated with acidification. A third member of the family, ASIC3, was cloned from its homology with ASIC1, and is expressed mainly in small sensory neurones (and was initially named

DRASIC – DRG specific ASIC – in recognition of this). The response of ASIC3 to acidification is, like ASIC1, extremely transient, though there is some evidence for a sustained component activated at very low pH. Finally, the last member of the family as currently known, ASIC4, has strong homology with ASIC1 and is expressed in sensory neurons, but does not respond to acid and so seems unlikely to have a role in signaling acid pain.

The main alternative possible role for the ASIC family suggested to date is in mechanosensation, a suggestion that arises by analogy with the role of the related MEC family in mechanosensation in *Caenorhabditis elegans*. ASIC2a and ASIC3 mouse knockouts do show small alterations in nonnoxious mechanosensation, but the effects are not large, and the evidence for an involvement of the ASIC family in mechanosensation is not, at present, overwhelming. In support of this view, a recent study of mechanically gated ion currents in isolated sensory neurons from ASIC2 and ASIC3 knockout mice found that these currents were similar to wild type in both low-threshold neurons (presumed detectors of nonnoxious mechanical stimulation) and in a class of neurons responding only to high-threshold mechanical stimulation (presumed mechanical nociceptors).

1.4 Ion Channels Gated by ATP

It would be sensible for pain to be signaled by the release of the contents of damaged cells; in which case ATP is a prime candidate for activating nociceptive nerve terminals, as it is present at high concentrations within cells and is practically absent from the external medium. Injection of ATP does indeed cause pain. ATP is known to act at two main classes of membrane receptors: ion channels of the P2X family, and G-protein-coupled receptors of the P2Y family. The first are implicated in direct activation of nociceptors and are discussed here, while P2Y receptors are involved in sensitization and are discussed below.

Cloning of the first member of the P2X family opened up the way for homology cloning of seven other members, of which $P2X_3$ would appear to be of particular significance for pain transduction, as it is expressed only in nociceptors. ATP or its analogs rapidly activate an inward current through $P2X_3$, but the current is only transient, a property which is, as was the case with the ASIC family, not obviously consistent with the need to generate a sustained sensation of pain in response to ongoing cell damage. Nociceptors from the autonomic nervous system generate a sustained inward current in response to ATP, a property that can be explained by coexpression as a heteromeric channel of $P2X_2$, which generates a sustained inward current, and $P2X_3$, which generates a transient inward current. Most nociceptors from the somatic nervous system, however, express only $P2X_3$ and generate a transient inward current in response to ATP and its analogs. While these observations are internally self-consistent, they do not favor the idea that $P2X_3$ receptors might signal somatic pain in a sustained manner. Consistent with this, acute pain signaling was relatively normal in $P2X_3^{-/-}$ mice, although the detection of warm stimuli was affected, an observation that is still not fully explained. Interestingly, the main defect present in these mice was the absence of a normal bladder-emptying reflex, consistent with the idea that expression of $P2X_3$ ion channels in nociceptive neurons of the bladder is essential for

bladder-emptying when a state of painful fullness has been reached.

1.5 Ion Channels Gated by Mechanical Stimuli

The first stimulus most people would think of in the context of pain is a strong mechanical stimulus, but, ironically, the ion channels involved in the generation of this most intuitively obvious of the pain sensations have proven the most elusive. Recent studies have identified inward membrane currents activated in isolated DRG neurons by direct mechanical stimulation either with a probe or following stretching of the membrane by swelling in hypotonic solutions. Two populations of neurons can be distinguished: those with a low threshold, which are capsaicin-insensitive and therefore are presumably nonnociceptive, and those with a higher threshold, which are, in general, sensitive to capsaicin and are therefore presumably nociceptive neurons. These two populations are likely to correspond to the two main observed classes of *in vivo* mechanoreceptors, which detect nonnoxious and noxious stimuli, respectively.

The molecular identity of the mechanically gated ion channel is still unclear, but two main possibilities are currently being considered. As discussed above under ''Ion channels gated by acid,'' the homology between the ASIC family and some members of the MEC family of ion channels, known to be mechanically gated in *C. Elegans*, has led to the proposal that ASICs form part of the mechanoreceptive complex, and there is some support for this proposal from gene knockout studies (see above). The mechanosensitive current is inhibited by calcium, a property that is reminiscent of the strong inhibition of ASIC-dependent currents by calcium, but, in other respects, the mechanosensitive currents do not obviously exhibit the properties of ion channels of the ASIC family. In particular, the amplitude of mechanosensitive currents is not correlated with that of acid-gated currents in DRG neurons; the mechanosensitive currents are not altered by acidification; and knockout of either or both of ASIC2 and ASIC3 has no effect on mechanically gated ion currents.

The second possibility is that a member of the TRP family may be involved. TRPV4 (originally called OTRPC4 or VR-OAC) generates an inward current in response to cell swelling, though the action appears to be via phosphorylation of TRPV4, rather than being a direct gating which would be more consistent with the known rapid response to noxious mechanical stimuli. Downregulation of *TRPV4* gene expression impaired the nociceptive response to injection of hypotonic solutions, and pressure sensation was reduced in TRPV4$^{-/-}$ mice. While these data are intriguing, they do not as yet provide unambiguous evidence for involvement of TRPV4 in mechanosensation, and other possibilities must remain open.

1.6 Initiation of Action Potentials by Noxious Stimuli

To be detected, all noxious stimuli must generate action potentials in the afferent nerve fiber. The first hint that this process may be different from that in other sensory neurons came when a voltage-sensitive sodium channel unique to nociceptive neurons was cloned in 1996 in John Wood's lab by a difference-cloning strategy. This channel, initially called SNS (*sensory neuron specific*) but subsequently renamed $Na_V1.8$, has two

main differences from most other voltage-dependent sodium channels: it is relatively resistant to tetrodotoxin, and the voltage at which it is first activated is more positive by about 20 mV than that of the widely expressed $Na_V1.2$ or $Na_V1.7$ channels. Significantly, the threshold of $Na_V1.8$ is modulated in the negative direction by inflammatory mediators such as prostaglandins, thereby making the neuron more excitable (see below).

A second TTX-insensitive sodium channel, $Na_V1.9$ (initially named NaN or SNS2), was subsequently identified. This channel, in spite of having a high homology to the other members of the Na_V family, seems not to be voltage-activated in the same way as other sodium channels, though it may generate a ''window current'' that contributes to maintenance of the resting potential. Surprisingly, this sodium channel has recently been shown to generate an inward current when directly activated by the binding of BDNF to TrkB receptors.

1.7 Summary Diagram of a Nociceptive Terminal

Figure 1 summarizes the ion channels currently known to be involved in excitation of the nociceptive nerve terminal. Typically, several different ion channels are expressed in a single nociceptor, thus conferring the property of polymodality commonly seen in nociceptors, but there is often, in practice, a more restricted expression than that shown in Fig. 1, leading

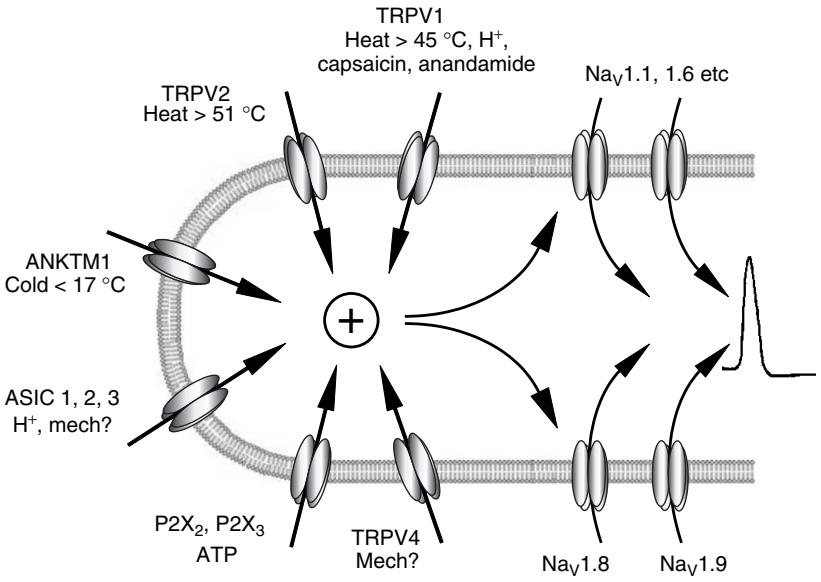

Fig. 1 Schematic diagram of ion channels activated by noxious stimuli in nociceptor nerve terminals. Ion channels responsible for activating inward current in response to noxious stimuli are shown at the left, along with the stimuli believed to be primarily responsible for their activation. Voltage-sensitive sodium channels activated by the consequent depolarization are shown diagrammatically on the right. Note that $Na_V1.9$ is not voltage-activated in the conventional sense, but, instead, appears to be activated by direct interaction with BDNF bound to TrkB.

to a somewhat greater degree of specificity in individual nerve terminals. An influx of current – usually carried mainly by Na^+ ions, though Ca^{2+} ions may also contribute – through any of the ion channels leads to depolarization and consequent activation of voltage-sensitive sodium channels, thus generating an action potential which propagates to the CNS. The sensitivity of the nociceptor to noxious stimuli can be modulated in two main ways: either by enhancing the generator current activated in response to a noxious stimulus, or by changing the threshold of the sodium channel so that the nociceptor is more readily excited. These possibilities are discussed below.

2 Sensitization by Inflammatory Mediators

Following tissue damage or inflammation, the sensitivity of nociceptive nerve terminals *in vivo* increases, a process known as *sensitization*. In the sensitized state, painful stimuli are enhanced (a phenomenon known as *hyperalgesia*) and ordinarily nonpainful stimuli are perceived as painful (*allodynia*). Sensitization is caused by the release of chemical mediators from surrounding damaged or inflamed tissue, because when nociceptive neurons are isolated they show only adaptation to repeated application of stimuli such as heat or capsaicin. The mediators capable of causing sensitization include prostaglandins, bradykinin, protons, ATP, and even nerve growth factor, and new physiologically important factors are being discovered at a high rate. The majority act via G-protein-coupled receptors and intracellular signaling pathways, though some may act directly (e.g. protons act directly on TRPV1). Sensitization has both short-term components, on the timescale of seconds and due to a local action of inflammatory mediators on nociceptive nerve terminals, and long-term components due to upregulation of gene transcription and a consequent change in the protein expression in the nerve terminal. The pathways involved are better understood in some cases than in others.

3 Short-term Sensitization: Mediators and Pathways

3.1 Bradykinin and the PKC Pathway

Bradykinin is a nonapepetide released by proteolysis of a precursor protein, kininogen, when proteolytic enzymes are released from damaged cells, and acts mainly at B2 receptors. Kininase I cleaves the C-terminal arginine to give des-arg^9 bradykinin, which is a potent activator of B1 receptors but largely ineffective at B2 receptors. Both B1 and B2 receptors are coupled to G_q and thence to PLCβ, leading to cleavage of PIP_2 and release of IP_3 and DAG. In 1996, we found that bradykinin potently enhances the heat-activated current, an observation that was made before the identification of TRPV1, but the downstream target is now identified as TRPV1 because a similar effect is seen in HEK293 cells transfected with TRPV1.

The following lines of evidence suggest that the pathway leading to sensitization of TRPV1 involves protein kinase C. PMA, a selective activator of PKC, has similar effects to bradykinin; staurosporine, a PKC inhibitor, blocks the effects of bradykinin; and phosphatase inhibitors prolong the effects of bradykinin. There are 11 isoforms of PKC, of which five (PKCβI, βII, γ, ε and

ζ) are expressed in neonatal DRG neurons, but only one isoform, PKCε, is involved in the sensitization of TRPV1 by bradykinin, because infusion of a constitutively active form of PKCε has similar effects in enhancing the heat-activated membrane current, and because a selective inhibitor of PKCε suppresses the action of bradykinin. Bradykinin causes a selective translocation of PKCε to the neuronal cell membrane, a sensitive indicator of PKCε activation. A later study showed that PKCα, which is expressed in more mature DRG neurons, but not in neonatal neurons, may also be able to activate TRPV1. The proposed pathway linking B2 receptor activation to TRPV1 activation is shown in Fig. 2(a).

Residues phosphorylated by PKCε have now been identified by site-directed mutagenesis. Serines 502 and 800 in rat TRPV1 are in the first intracellular loop and in the C-terminal tail respectively (see Fig. 2(b)), and replacement of both these residues by nonphosphorylatable alanines was found to completely abolish the enhancement of TRPV1-dependent current caused by activation of PKCε. All of the effects of PKCε on TRPV1 would therefore seem to be mediated by phosphorylation of these two residues.

A second mechanism for the action of bradykinin on TRPV1, independent of PKC activation, has also been proposed by the group of David Julius. Removal of PIP2 from the membrane, either by hydrolysis or with an antibody, reduced the action of bradykinin and NGF in expression systems, suggesting that PIP2 associates with and inhibits TRPV1, and that removal of PIP2 is the crucial factor in enhancing TRPV1 following activation of PLC. The relative importance of this second mechanism for the action of bradykinin in sensory neurons, as opposed to in expression systems, has yet to be investigated, but the observations that application of kinase inhibitors removes most or all of the enhancement caused by bradykinin

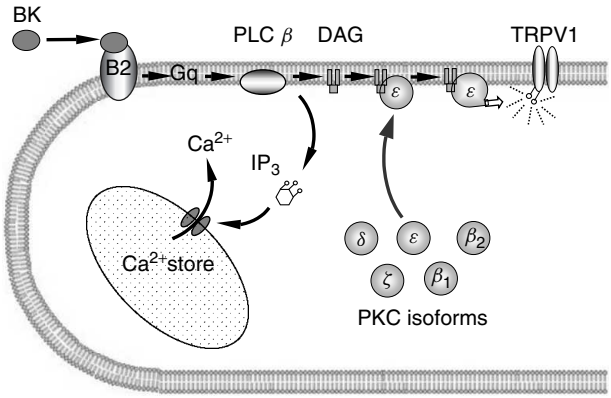

Fig. 2a Pathways leading to sensitization of TRPV1. Binding of bradykinin to the B2 receptor leads to activation of phospholipase C and release of IP_3 and diacylglycerol. Of the five PKC isoforms expressed in nociceptive neurons, only PKCε is translocated to the membrane by bradykinin. Activation of PKCε by bradykinin leads to phosphorylation of TRPV1 and enhancement of the membrane current gated by a heat stimulus.

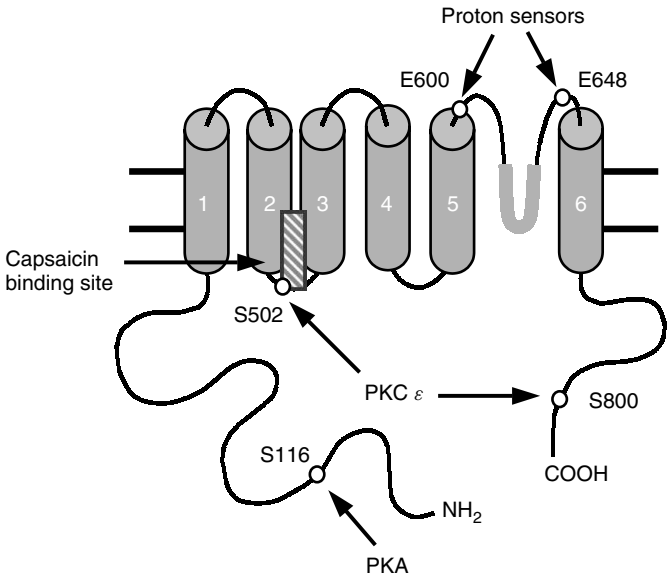

Fig. 2b Targets of sensitization on TRPV1 (numbering of sites for rat TRPV1). The binding site for activation by capsaicin is shown. Target sites include intracellular serines, which are phosphorylation sites for PKCε and PKA, and extracellular glutamates whose protonation also modulates gating (see text).

(see above) suggests that it plays a lesser role than the PKCε pathway shown in Fig. 2(a).

3.2 Prostaglandins and the PKA Pathway

Arachidonic acid is released from membrane lipids by the action of phospholipase A_2 in response to a wide range of damaging and stressful stimuli, and is the precursor for a vast range of proinflammatory mediators, including leukotrienes, lipoxins, thromboxanes, and prostaglandins. PGE_2 and PGI_2, which are both produced downstream of the cyclo-oxygenase (COX) enzymes, are particularly important mediators of hyperalgesia, and the inhibition of their production by COX inhibitors such as aspirin explains the potent analgesic effect of these inhibitors. When PGE_2 is applied to nociceptive neurons, the threshold of the TTX-insensitive sodium current shifts in the negative direction, leading to a decrease in the threshold for eliciting an action potential and, consequently, an increase in excitability in response to a wide range of noxious stimuli. Activation of adenylate cyclase with forskolin has a similar effect, suggesting that the cAMP/PKA pathway is important in this action of PGE_2. In agreement with this idea, it was found that the effect could be abolished by mutating five serine residues, all of which are consensus sites for PKA and are located on the first major intracellular loop of $Na_V1.8$. Thus, an important part of the action of PGE_2 can be attributed to phosphorylation of $Na_V1.8$ by PKA, as shown in Fig. 3.

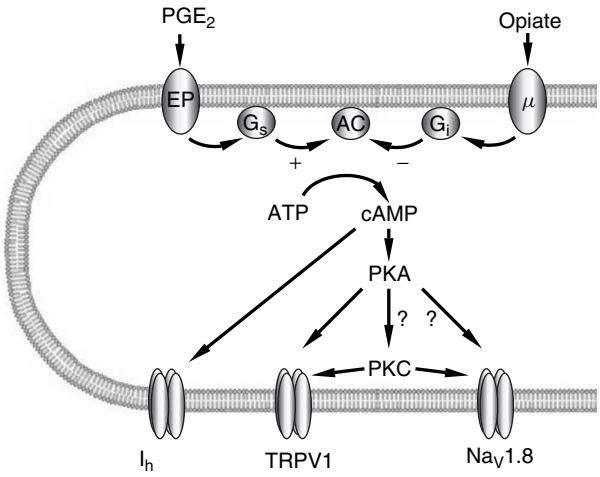

Fig. 3 Intracellular pathways and targets of the cAMP/PKA pathway causing nociceptor sensitization. An indicative proalgesic agent (PGE_2, binding to a receptor of the EP family) and an analgesic agent (an opiate, binding to the μ opiate receptor) are shown, but it seems likely that a number of other agents, both proalgesic and analgesic, will activate the same pathways.

An alternative possibility was suggested by studies in which PKA and PKC were each blocked by selective inhibitors. Activation of PKC alone increased the TTX-resistant sodium current (but apparently without the shift of threshold caused by PKA activation), and the increase was not blocked by PKA inhibitors, while the increase in current caused by PKA activation was blocked by PKC inhibitors. These experiments suggest that the pathway linking PGE_2 application to an increase in current through $Na_V1.8$ may be PKA → PKC → $Na_V1.8$. This result is not necessarily incompatible with the finding mentioned above, that is, that mutating consensus sequences for PKA abolishes modulation of $Na_V1.8$, as many potential phosphorylation sites are surrounded by adequate consensus sequences for both PKA and PKC. It seems likely that $Na_V1.8$ is targeted by both kinases, but the relative importance of each for the observed increase in TTX-insensitive sodium current and shift in excitation threshold has not been completely disentangled.

PKA also targets TRPV1. While phosphorylation by PKC directly enhances the heat or capsaicin-gated current, as described above, phosphorylation by PKA has the more subtle effect of reversing the desensitization caused by prolonged or repeated activation of TRPV1. Although more than one site is phosphorylated by PKA, the reversal of desensitization is abolished by mutating just a single serine, 116 in the rat TRPV1 sequence. The action of PKA on TRPV1 depends on anchoring by an A-kinase-anchoring protein (AKAP), suggesting the formation of a signaling complex in which AKAP anchors PKA to TRPV1 in order to achieve rapid and reproducible physiological modulation of the membrane current gated by heat (Fig. 3).

The cAMP produced by activation of adenylate cyclase may also have a direct effect in modulating the voltage sensitivity of I_h ion channels, which pass an inward current and are activated by hyperpolarization. Members of this family have a cyclic nucleotide binding site near the C-terminal, and binding of, for example, cAMP shifts the activation range in the positive direction, which has the effect of increasing the inward current and therefore of hastening depolarization to threshold for initiation of the next action potential. I_h plays a crucial role in many tissues, including heart, where it mediates the pacemaker potential, and neurones, where it determines the firing frequency by modulating the rate at which the membrane potential depolarizes between action potentials. Four channel subunits, HCN 1–4, have been cloned. I_h has been reported in nociceptors, where it may play an important role in modulating firing in response to agents that modulate cAMP, such as prostaglandins, sympathomimetic monoamines, or opiates.

Opiates have well-known and potent central analgesic actions, but it has recently been shown that they also have a peripheral analgesic action. Binding of agonist to the μ opiate receptor expressed on nociceptors activates G_i, thus causing an inhibition of cAMP production and consequently antagonizing the proalgesic actions of (for example) prostaglandins. A peripheral analgesic action for cannabinoids has also been suggested, but whether the cAMP pathway is involved in the same way as it is for opiates has yet to be established.

3.3 Nerve Growth Factor

Activation of mast cells by a stimulus such as bacterial lipopolysaccharide (LPS) causes release of nerve growth factor (NGF), which is a potent, though perhaps surprising, inflammatory mediator. NGF injection causes a rapid and long-lasting thermal hyperalgesia, and a mechanical hyperalgesia with a slower onset. NGF is involved in physiologically significant hyperalgesia *in vivo*, since removal of NGF reverses both the thermal and the mechanical hyperalgesia caused by an injection of LPS. There is general agreement that the long-term effects of NGF are due to upregulation of gene expression (see below), but the short-term effects, which can be seen *in vivo* within minutes of injection of NGF, must be due to activation of local signaling pathways within the nerve terminal. Rapid effects of NGF on TRPV1 *in vitro* have been characterized in isolated neurons using whole-cell patch clamp and calcium imaging, and show that an enhancement of the current passing through TRPV1 is induced within 2 min of exposure to NGF. TRPV1 gating is enhanced by NGF in around 40% of TRPV1-expressing neurons, a proportion that agrees with immunocytochemical experiments in which it was found that about 50% of nociceptive neurons express TrkA receptors for NGF.

The identity of the pathways activated by NGF and leading to sensitization of TRPV1 is currently the subject of some disagreement. Activation of TrkA receptors by NGF recruits many signaling molecules that can bind to the intracellular phosphorylated tyrosine residues within TrkA by means of Src homology (SH2) domains. Three proteins, in particular, have been identified on the basis of their specific binding to phosphorylated Trk receptors: Shc, which activates the Ras/MEK pathway; phospholipase C gamma-1 (PLCγ1), which cleaves PtdIns-4,5-P_2 to IP_3 and

DAG; and phosphatidylinositol-3-kinase (PI3K), which 3-phosphorylates PtdIns-4,5-P_2. Many other signaling molecules are possible secondary mediators of the physiological effects of TrkA activation. Mendell's group has proposed that PKA is an essential downstream element, as PKA inhibitors abolished the NGF-induced sensitization in patch clamp studies, while inhibitors of PKC and MAP kinase were without effect. Work from the group of David Julius has proposed a quite different mechanism, independent of phosphorylation: activation of PKCγ by TrkA, which is known to lead to breakdown of PIP2, may remove PIP2 from binding sites on TRPV1, releasing it from PIP2 mediated inhibition. This mechanism would unify the sensitizing actions of a number of agents, including bradykinin, NGF, ATP acting at P2Y receptors, and others, which have in common that they activate PLC. In our lab, we have used calcium imaging of intact neurons to investigate signaling pathways activated by TrkA, and our conclusions are again different: we find that wortmannin, a selective inhibitor of PI3 kinase, totally abolishes sensitization, while inhibition of PLC-γ is without effect, suggesting that PI3 kinase, and not PLCγ, is the crucial early step. MEK inhibition had no effect on NGF-induced sensitization, showing that the MEK/MAPK pathway is not involved, at least downstream of MEK, while ras inhibition had a small inhibitory effect on sensitization, consistent with a modulation of PI3K by ras, as shown in other studies. We have also found that inhibitors of PKC and CAM kinase abolish sensitization, suggesting an involvement of these kinases at a later stage, though the details of the later stages of the signaling pathway are currently unclear. The observation that kinase inhibitors abolish NGF-induced sensitization suggests that phosphorylation of TRPV1 is an essential final common pathway, as with sensitization in response to other inflammatory mediators discussed above, but the kinases involved, and the residues on TRPV1, which they phosphorylate, have yet to be identified.

3.4 Direct Modulation of TRPV1 by Protons

The acid produced by inflammation or during ischemic exercise, where pH levels may fall as low as 5.4, is an important contributor to pain. As discussed above, protons may cause pain directly by an action at either or both of TRPV1 or members of the ASIC family, but protons can, in addition, sensitize the response of TRPV1 to heat, without directly activating it, by shifting to lower temperatures the relationship between channel activation and heat, in much the same way as bradykinin does. The relevant residues have been identified as two glutamates near the mouth of the channel, one of which (E600) is involved in setting the sensitivity of the channel to heat, while a second (E648) is involved in direct activation of the channel. It is interesting to note that two actions on opposite sides of the membrane – protonation at an external site, and phosphorylation by PKC at an internal site – can have rather similar effects in terms of modulating the sensitivity of the TRPV1 ion channel to heat.

3.5 Other Modulators of Nociceptor Sensitivity

In a highly evolved system such as nociception, a wide variety of factors released by injury or inflammation would be expected to cause hyperalgesia, and the

few factors outlined above are only the best understood amongst many. The following list outlines what is known of some others, but this list is sure to be far from complete.

3.5.1 ATP

The best-characterized action of ATP is in activating P2X ion channels and thus directly exciting nociceptors, but a sensitizing action arising from an action at P2Y receptors may be more important *in vivo*. Through an action at the $P2Y_1$ G-protein-coupled receptors, ATP activates the same pathway as bradykinin, that is, PLCβ, releasing DAG and leading to activation of PKCε and consequent phosphorylation of TRPV1, as shown in Fig. 2a.

3.5.2 Proteases

Proteases released following cell damage activate a family of protease activated receptors (PARs), in which proteolysis of the extracellular N-terminal domain leads to unmasking of a tethered agonist peptide and consequent receptor activation. In intact animals, prolonged hyperalgesia results from injection of PAR activators, and PAR2 seems to be particularly involved in the generation of itch. Downstream pathways involve PLC, leading to intracellular calcium signals and consequent exocytosis of neuropeptides, and ERK activation may also play a role.

3.5.3 Bv8/Prokineticin

Bv8 is a small protein isolated from amphibian skin whose mammalian homologs are the prokineticin family. The receptors for these proteins, PKR1 and PKR2, are expressed in mammalian DRG neurons, and injection of Bv8 leads to a profound and long-lasting thermal and mechanical hyperalgesia in intact animals. Application of Bv8 to isolated DRG neurons causes calcium release from intracellular stores, suggesting that an activation of the PLC pathway may be the basis of the sensitization. While these observations are tantalizing, there is as yet no evidence that prokineticins are actually released during inflammation, nor what component of physiological hyperalgesia may be due to activation of PKRs.

3.5.4 Glutamate

The possibility that glutamate may play a role in hyperalgesia was raised by the observation that the metabotropic glutamate receptors mGluR1 and mGluR5 are expressed on C-fiber afferents, and that injection of agonists of these receptors causes thermal hyperalgesia. The observation that antagonists partially suppress the pain caused by formalin injection suggests a physiological role for glutamate in pain. Current understanding of the intracellular pathway is that PLC is activated by mGluR, but the main downstream effect is not to activate PKC, but, instead, to cause release of prostaglandins and TRPV1 sensitization via a PKA-dependent pathway.

3.5.5 Norepinephrine

Activation of β_2 receptors by norepinephrine (noradrenaline) or other adrenergic agonists causes a hyperalgesia which is reduced in PKCε KO mice or when PKCε is inhibited, suggesting an involvement of PKCε downstream of β_2 receptor activation. The target of PKCε when activated by norepinephrine has not been clearly established, and could be TRPV1, as is the case when bradykinin receptors are activated (see above, Fig. 2) and/or $Na_V1.8$. More recent work has suggested that the

ERK/MAPK pathway may, in addition, be an important mediator of sensitization caused by β_2 activation.

4
Long-term Sensitization

Pain is usually transient in nature, disappearing quickly when a mild noxious stimulus is removed, or more gradually as the inflammation caused by an injury dies away. Some forms of pain, however, notably those caused by nerve injury, can be much longer lasting, suggesting that long-term changes in gene expression underlie them. Long-lasting pain caused by nerve injury is called *neuropathic pain*, and its origin is currently the subject of much debate. Long-term changes in transmission to second-order neurons in the spinal cord are important, but phenotypic changes in the ability of primary sensory neurons to detect painful stimuli or to sensitize in response to inflammatory mediators also play a role.

Growth factors play a crucial role in the control of nociceptor phenotype. Neonatal neurons depend on NGF for survival, but in the adult animal, removal of NGF does not cause cell death but, instead, changes the expression of many proteins associated with the nociceptive phenotype. A reduction in NGF supply can be caused by nerve section, which removes the supply of target-derived NGF from innervated tissues. The supply of neurotrophins can also be increased in some circumstances – for instance, NGF is known to be released from mast cells and other sources during inflammation, and both NGF and GDNF are released from invading macrophages when nerve axons degenerate following nerve damage. Thus NGF and GDNF will bathe any surviving axons in the damaged nerve trunk in a neurotrophin-rich fluid.

4.1
Gene Expression Regulated by NGF

The expression of the neuropeptides substance P and CGRP was shown a number of years ago to be downregulated by NGF removal or, conversely, upregulated by addition of NGF, while other neuropeptides such as VIP and CCK are upregulated by NGF removal. One effect of an oversupply of NGF may, therefore, be to enhance peptidergic neurotransmission by substance P and CGRP at the first synapse, while deprivation of NGF, caused for instance by nerve section, would have the converse effect. TRPV1 expression is upregulated by NGF in a pathway that depends upon activation of ras and the MEK/MAPK cascade. Work in our own lab has shown that expression of the bradykinin B2 receptor is also upregulated by NGF.

One of the prominent physiological changes in nociceptors following nerve damage involves the generation of sustained action potential firing, and a neurotrophin-driven change in sodium channel expression may be a contributor to this. The expression of $Na_V1.8$ is upregulated by NGF and, conversely, is downregulated by nerve section. This last observation would not appear to offer a ready explanation of neuropathic pain, in which we would be looking for an upregulation of the expression of $Na_V1.8$ following nerve damage in order to explain repetitive activity, but other evidence suggests that in neuropathic pain states $Na_V1.8$ may, in fact, be upregulated in nerve trunks, if not in the neuronal cell body. A second channel, $Na_V1.3$, is not normally expressed in sensory neurons but appears after nerve damage, and has

characteristics that may make it a candidate for the originator of the repetitive firing seen following nerve damage.

A second possible contributor to the repetitive firing observed following nerve damage is the hyperpolarization-activated inward current channel, I_h, which contributes to action potential firing by regulating the rate at which the neuronal membrane depolarizes between action potentials (see above). Recently, it has been suggested that I_h may be functionally enhanced in neuropathic pain states, as a blocker of I_h, ZD7288, alleviated neuropathic pain. Surprisingly, I_h protein and mRNA expression was found to be downregulated in an experimental neuropathic pain state, but the magnitude of the I_h current nonetheless increased, perhaps because the voltage dependence of the current is shifted in the depolarizing direction.

4.2 Gene Expression Regulated by GDNF

Only around half of nociceptors express TrkA receptors for NGF, while the other half express Ret receptors for GDNF. Many of the nociceptor-specific proteins expressed by these two groups of neurons are different: the TrkA-expressing neurons also express the neuropeptides substance P and CGRP and terminate in outer layers of the dorsal horn (layer I and II outer), while the Ret-expressing neurons express surface receptors binding to the plant lectin IB4 and terminate in layer II (inner) of the dorsal horn. These two populations might be considered the ''rods and cones'' of the nociceptor system, but so far no very distinctive differences in their properties have been characterized, at least not to match those conferring differential wavelength selectivity and time course on the visual rod and cone systems.

Ability to bind IB4 provides a convenient method for distinguishing the two nociceptor populations, as it can be readily applied both to living and to fixed neurons. Several nociceptor-specific proteins are localized to the IB4-positive population: both the P2X3 receptor for ATP and the $Na_V1.9$ sodium channel are exclusively located in the $IB4^+$ neuronal population, and our group has identified B1 bradykinin receptors as also being exclusively located in $IB4^+$ neurons, unlike B2 receptors, which are expressed mainly in $TrkA^+$ neurons.

Ret forms functional receptors for members of the GDNF family, which, apart from GDNF itself, comprises the elegantly named members neurturin, artemin, and persephin, by combining with the GFRα receptor family, although there is some evidence that Ret may be active alone. By analogy with the action of NGF in upregulating gene expression in TrkA-expressing neurons, we might expect that GDNF and other members of this family would have a similar effect in upregulating the proteins expressed in the $IB4^+$ neurons, but, to date, this possibility has been little investigated. A recent report, however, shows that B1 expression is potently upregulated by GDNF. B1 receptors are normally expressed in only a very small fraction of neurons (around 2%), but, following exposure to GDNF functional B1 receptor expression, appear in around 20% of neurons. GDNF or related neurotrophins are therefore likely candidates to drive upregulation of B1 expression following injury or inflammation, leading to the switch in agonist responsiveness from a B2 to a B1 profile identified in *in vivo* experiments.

5 Conclusion

There has been an explosion of research into the cellular and molecular basis of pain transduction over the past few years. Many of the membrane ion channels responsible for the detection of painful stimuli have now been cloned, and we are making good progress in identifying the intracellular pathways responsible for modulating these ion channels and thus mediating the process of sensitization. Some areas are still mysterious and will no doubt form the subject of advances in understanding in future years. We still know little about the molecular basis for detection of strong mechanical stimuli (or, indeed, any mechanical stimuli). The means by which temperature-sensitive ion channels are gated still remains unknown at the molecular level. Much remains to be discovered about the pathways mediating sensitization – kinases seem to be important in most of the pathways investigated to date, but the details of how they are activated, and which are their critical target residues on the primary transducer ion channels, still remain, in many cases, to be elucidated.

Keywords

Ancient DNA
Deoxyribonucleic acid isolated from ancient tissue sources; the most common method for isolation of DNA from ancient tissue sources is through the polymerase chain reaction.

Biomarkers
Chemical or biochemical structures that were once a part of the biomass of a living ancient organism; also known as molecular fossils.

Fossilization
The preservation of deceased organisms via mineralization, mummification, compression, or amberization.

Mineralization, Amberization, and Mummification
The process of fossilization that preserves materials for examination at the molecular level.

Paleontology
The study of the structure, composition, and behavior of dead organisms.

Recent developments in modern molecular biology have facilitated the expansion of the new field of molecular paleontology. This field comprises the isolation and characterization of proteins and nucleic acids from fossil material. The various kinds of fossil preservation are outlined and discussed with respect to the types of preservation most appropriate for producing fossils that will yield direct sequence information. The molecular techniques used to isolate nucleic acids and proteins, and to characterize the sequence information from these molecules are described. The biological importance of data obtained from fossils is also discussed.

1 Definitions

1.1 Paleontology

Paleontology is defined as the study of ancient organisms. Paleontological information has been recognized as an important aspect of evolutionary biology since before Darwin's time. Indeed, Darwin dedicated an entire chapter of *On the Origin of Species* to an examination of the fossil record. Darwin was preoccupied with the incompleteness of the fossil record and was concerned with the degree to which it supported his theory of natural selection. Several other examples of the influence of fossils on modern biology can

be cited, such as the discovery of entire groups of unusual organisms that have gone extinct (dinosaurs), the characterization of mass extinctions, and the use of the fossil record to calibrate divergence times in species comparisons. The utility of fossils for stratigraphic and chronologic correlations have also been repeatedly demonstrated.

1.2 Molecular Paleontology

The term *molecular paleontology*, at first was meant to include only the study of biological marker compounds, or biomarkers (organic molecules that were originally part of the biomass of an ancient organism, and have been preserved in rocks and molecules from fossils). The term has come to include the study of molecular information, both chemical and biochemical, potentially available from fossilized remains. (*Chemical fossil* is a broad term covering atomic and molecular fossils, including isotopic features.) More recently, molecular paleontology has been redefined to include historical information derived from comparisons of molecules of living organisms. A subbranch of molecular paleontology that concerns nonfossilized material from deceased organisms is known as *molecular archaeology*. Examination of recently deceased organisms at the molecular level is considered to be a part of molecular forensics. In the past, paleontological studies have provided information on ancient organisms only at the morphological level. With the development of gas chromatography, mass spectrometry, scanning and transmission electron microscopy, and modern molecular biology, the molecular aspects of fossils and subfossils have been explored. Three major kinds of molecular information can be recovered from fossils. The first is made of visual structural information using various forms of microscopy. Thin sections of microorganisms observed under microscopy have demonstrated the feasibility of this approach, and several fossil microscopic molecular structures have been observed this way. The second kind of molecular data consists of compositional information. Ancient atmospheric conditions as well as the chemistry of the ancient oceans have been examined using chemical composition information from fossils. Chemical and biochemical fossils have been examined for molecular structure by means of combined gas chromatography and mass spectrometry. Some information on the amino acid composition of tissues has been obtained from fossil and subfossil materials. Radioimmunoassay (RIA) techniques have also been used to examine the immunological distances of extinct organisms with their living relatives. The newest and perhaps most exciting class of molecular information obtained from fossils is the analysis of the actual genetic material of fossils, subfossils, and recently extinct organisms.

2 Fossilization

2.1 Types of Fossilization

The condition of the fossilized material is critical to the recovery of molecular information from any fossil. The depositional environment and the rock matrix where the fossil is deposited and the degree of decomposition of the fossil are critical factors in determining the state of the fossilized material. Fossilization of an organism is an extremely rare event; if it is going to occur,

it begins immediately after the death of the organism. In general, only a small portion of the organism is preserved. After death, an organism's body undergoes three types of decomposition. The first is biological and is accomplished by the decompositional activity of bacteria and by autolytic enzymatic processes. Bacteria are ubiquitous in environments with oxygen, so only organisms that are deposited into oxygen-free environments, hence able to escape bacterial decomposition, will have soft body parts preserved in any detail. The second type of decomposition is mechanical; it is facilitated by waves, wind, and other forms of abrasion. The final type of decomposition is chemical, which can proceed well after the fossilization process has begun. Ancient organisms can be divided into three categories: organisms that have been preserved through mineralization (mineralized fossils); organisms that have been preserved in amber (amber fossils); and organisms that have been preserved but not mineralized or amberized (subfossils and compression fossils).

2.2 Mineralization

Several types of mineralization can occur in the fossilization process, and each results in differences with respect to tissue preservation and the degrees of decomposition that occur in the organism. Mineralization usually produces fossils in which the molecules of the preserved organism have been replaced by minerals. Such fossils will be entirely devoid of organic molecules because all molecules in the organism will have been replaced or displaced by mineral matter. *Permineralization* is the impregnation of an organism with mineral materials, most frequently calcium carbonate and silica. Such a process produces a structure that is resistant to chemical change or chemical decomposition. *Metasomatism,* produced from the exchange of existing minerals for new minerals, yields a fossil that retains its physical appearance but undergoes a drastic change in chemical composition. In another process, the oxygen, hydrogen, and nitrogen molecules in plant remains are sometimes *leached* away, leaving a carbon residue that retains the original structures of the plant. *Incrustation,* in turn, produces fossilization, most frequently in more recent organismal material. When calcium-rich water flows over the remains of organisms they are covered with a *mineral film.* The organic material under the film then decomposes, leaving only a negative impression on the mineral layer. In the *distillation* process, water and gases are distilled away from the organism leaving on the rock a thin film of carbon that sometimes can give rich information on the structure of the distilled organism. Some tissues may be more resistant to the mineralization processes than others. Chitin and keratin are among the compounds found in organisms that are rather resistant to chemical decomposition and mineralization. Minerals such as apatite (teeth and bones of vertebrates) and calcium carbonate (shells of invertebrates) often form very resistant structures and parts of organisms. Chitinous exoskeletons of arthropods can be resistant to chemical decomposition by mineralization. Other proteins and nucleic acids (DNA and RNA) are much more susceptible to decomposition. Some depositional conditions produce fossils remarkably resistant to chemical decomposition and complete mineralization. The Solenhofen deposits in Bavaria and the Clarkia fossil beds of northern Idaho are excellent examples of this type of fossilization. Here,

organisms were deposited in an extremely low oxygen setting and rapidly buried in fine sediment. Because of the rapid burial and low oxygen availability, chemical and biological decomposition have not disturbed the organic material. During such a process, organisms are deposited in a very fine laminated sediment and preserved between two extremely thin sedimentary layers. The layers are usually found as shale deposits, and the organic material is usually preserved in extreme detail. In such deposits, it is actually possible to remove the remains of organisms from between the shale layers, and considerable ultrastructural preservation can be observed from these organisms.

2.3 Amber, Mummies, Subfossils, and Museum Collections

These forms of fossilization may leave remarkably well-preserved organismal remains as well as preserve organic material suitable for molecular studies. *Amberization* is caused by the flow of resinous material from several plant sources. The sites and ages of the major amber deposits on the face of the earth vary greatly. These deposits yield amber-preserved specimens from a wide range of animals, plants, protists, and bacteria. The common factor in the quality of the material found in amber is the thorough dehydration and protection of encased organic material. When the chemicals in amber (primarily diterpenoids) link together, trapped organic material dehydrates and becomes inert. (An excellent review of the biochemistry of amber formation was provided by Langenheim.) The ability of the flowing resin to completely encapsulate an organism and the bactericidal activity of terpenes in the resin suggest that amberization will produce highly protected fossil specimens. The most famous of these deposits are found from the Oligocene of Romania and the Baltic region and from the Miocene of the Dominican Republic, Mexico, Sicily, and the Apennines of Italy.

Natural desiccation (*mummification*) is yet another form of fossilization that can preserve ancient material in a form suitable for molecular analysis. This type of fossilization is extremely rare and involves almost complete preservation of the encased organism. An example of this kind of preservation from the Cretaceous is the anatosaurus, a dinosaur that was preserved complete with wrinkles in its skin. The specimen was preserved in this way as a result of extreme dehydration of the animal. Such preservation most likely occurs if the organism is deposited not in a submarine sedimentary basin but, rather, in unusual terrestrial environments. More recent examples of mummification are the ground sloth (*Mylodon*) and other smaller mammals of about 13 000 years ago from the Ultima Esperanza Cave in Chile, bog-preserved human remains of about 8000 years ago from the Windover Pond region of Florida, and animals of about 10 000 years ago preserved in California's La Brea tar pit. Permafrost-preserved organisms have also been used as a source of ancient material. The most famous is the woolly mammoth found in 40 000-year-old permafrost and the Neolithic human remains (named Oetzi) found in the Alps and believed to be 4000 to 5000 years old. Human cultural practices also result in mummification or preservation of organisms. The detailed preservation by the ancient Egyptians of the bodies of humans and some domestic animals is well known.

Other examples of more recently preserved remains exist. Nonmineralized (subfossil) remains of bones and teeth,

seeds, and even soil extracts have been used in ancient DNA studies. DNA from museum-preserved specimens of an incredibly diverse and large number also can be designated as ancient DNA. Teeth, bones, pieces of skins, feathers, alcohol-preserved specimens, and some pinned insects have all been used as sources of material for molecular studies. The Quagga study was the first study to extract DNA from museum specimens. Numerous studies on historical materials from excavations and museum collections representing varied taxa and tissues have followed. The continued importance of museum-derived collections should be emphasized as a source of ancient specimens for study.

Not all museum material is suitable for molecular analysis, however, inasmuch as some of the preservation procedures used by museum curators are rather hydrophilic and produce massive damage to the specimen at the molecular level. Table 1 lists several sources of animal and plant material successfully yielding DNA from specimens dating from the Pleistocene and Holocene.

2.4 Quality of Molecules from Ancient Sources: Proteins

Tissues and molecules react very differently in living organisms and under

Tab. 1 Pleistocene and Holocene specimens yielding ancient DNA.

Preservation condition	*Material extracted*	*Taxon*	*Age of specimen [years before present]*
Dry remains			
	Animal bones and teeth	Ground sloth	13 000
		Cave bear	20 000–130 000
		Moa	3350
		Saber-toothed cat	14 000
		Horse	25 000
		Woolly rhinoceros	40 000–70 000
	Plant material	Maize	3400
		Wheat	1200
	Temperate cave sediments	Two species of moa, and 29 plant taxa	600–3000
	Parasites	Endogenous retrovirus-like element from woolly mammoth	13 000–26 000
	Coprolites	Shasta sloth coprolite recovering both sloth and ingested plant DNA	Late Pleistocene
Frozen remains			
	Siberian permafrost	Woolly mammoth	13 000–33 000
	Beringian permafrost	Brown bear	14 000–42 000
	Alpine permafrost	Human (Oetzi)	4000
	Permafrost soil	19 different plant taxa and mammoth, bison, and horse	10 000–400 000

conditions of fossilization. For this reason, different tissues, and molecules undergo varying degrees of degradation and breakdown as fossilization proceeds. Amino acids were among the first types of molecule examined in fossils. By continuously etching fossil clamshells, the existence of amino acids throughout the fossilized material was demonstrated. Contamination as an explanation for the discovery of fossil amino acids was ruled out on the basis of three observations. First, several mollusk shells from the same sedimentary deposit were examined for amino acid content and substantial qualitative and quantitative differences were observed from shell to shell. If there had been contamination from the surrounding sediment, the amino acid contents would have been similar. Second, in binding experiments the two most common amino acids found in fossils have little if any affinity to calcium carbonate, and therefore these substances (glycine and alanine) are highly unlikely to have been absorbed from groundwater. Finally, the sediment surrounding the fossils was examined and the amino acid content was determined to be minimal. The relative amounts of each amino acid in several fossils was calculated over geological time. From studies of this type, the conclusion emerged that relative abundances of amino acids prepared from specimens from the various geologic ages show similar but distinct patterns. The results of examining the amino acid content of amberized insect fossils, suggest that the degree of preservation of amino acids in amberized materials, though high, varies from specimen to specimen. Typically, in proteins that have been fossilized, the peptide bonds between amino acids will be rapidly degraded. Under special circumstances, especially in shells and skeletal remains, peptide bonds will remain intact and short peptides will be preserved. The position of proteins between (inter-) and within (intra-) crystalline structures in a fossil will affect the longevity of fossil molecules. Intracrystalline molecules would be expected to have greater survival potential as a result of the protective aspects of the surrounding crystal structure. The examination of fossils of several marine organisms with shell structures has revealed a rapid decline in the abundance of amino acids in the first few hundred thousand years after death. The degree of decomposition usually levels off at 2% surviving amino acids. Soluble and insoluble organic residues are also important factors in determining the degree of preservation of amino acids and peptide fragments in fossils.

2.5 Quality of Molecules from Ancient Sources: Nucleic Acids

Nucleic acids and DNA, in particular, would be expected to be much less well preserved in fossil materials than some proteins. DNA is primarily concentrated in soft tissues, which are highly susceptible and vulnerable to degradation during fossilization. The stability of the DNA double helix has been discussed at length by Lindahl. Basically there are three major modes of chemical and physical destabilization to the double helix: DNA hydrolysis, DNA oxidation, and nonenzymatic DNA methylation (Table 2). The stability of the nucleic acid phosphodiester bond that links one nucleotide to another in both deoxyribonucleotide strands and ribonucleotide strands is gained at the cost of a labile *N*-glycosyl bond. This bond connects the sugar ring of the nucleotide to

Tab. 2 Process of destabilization of the DNA double helix as discussed by Lindahl.

Process	*Effect*	*Target*	*Rate*
Hydrolysis			
I	Base sugar bonds destroyed	*N*-glycosyl bonds of G and A	Up to 10 000 purine bases removed in human cells per day
II	Deamination	Cytosine	Half-life of C residue in double-stranded DNA estimated at 30 000 years
III	Conversion of C to U	Cytosine	Not determined
Oxidation			
I	Hydroxylation of G to produce 8-hydroxyguanine	Guanine	Occurs 100–500 times per day in human cells; ''indirect and imprecise''
II	Ring-saturated derivative of a pyrimidine	T and C	Not determined; ''indirect and imprecise''
III	Major helical distortions	G and A	Not determined
Methylation	S-adenosyl-methionine (SAM)	Ring nitrogens; purines; G, A, T, C	600 alkylation events in the human cell per day

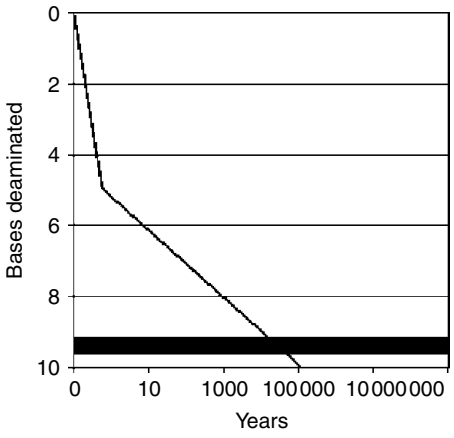

Fig. 1 Graph of time on a logarithmic scale versus the number of bases deaminated, also on a logarithmic scale. The numbers on the bases-deaminated axis refer to the log of 10 molecules deaminated. The figure was drawn by extrapolation from the published lower rate of deamination as 2000 bases per day. Stippled bar at the bottom indicates the cutoff for the genome size of humans (10^9 bases per haploid genome).

the base of the nucleotide. It was discovered by means of hydrolysis experiments that guanine (G) and adenine (A) are liberated almost 20 times more easily than thymine (T) and cytosine (C), indicating that depurination (loss of G and A) is much more common under hydrolysis than the loss of pyrimidines (T and C). The hydrolysis of the DNA double helix would result in lesions in single and double-stranded nucleic acids. The half-life of single-stranded DNA due to hydrolysis in solution at pH 7.4 and at 37 °C was calculated to be about 200 years. The half-life of double-stranded DNA under similar conditions due to hydrolysis was estimated at 30 000 years (Fig. 1). It has been estimated that this process of hydrolysis

causes the depurination of 2000–10 000 purine residues everyday in the typical human cell. The cell can tolerate such a high degree of depurination due to hydrolysis because enzymes exist in the living cell to repair the damaged regions of the double helix. In fossilized cells, repair enzymes would most definitely be inactive, with the result that any damage to the DNA in a fossilized cell does not get repaired. Active oxygen is an important source of damage to nucleic acids in growing cells. Degradative processes due to oxidation can cause oxidative damage to occur in several places along the DNA double helix (Table 2). The major product of this kind of damage to DNA is the conversion of guanine residues to 8-hydroxyguanine; indeed, this process and the hydrolytic deamination of cytosine to uracil are the two most prevalent mutagenic events in living cells. Two other products of oxidative damage to DNA are ring-saturated derivatives of pyrimidines and the production of major helical distortion. Estimates of the frequency of the most common oxidative damage (oxidation of guanine to 8-hydroxyguanine) are around 100–500 residues per day per human cell. These estimates are an order of magnitude less than that for hydrolysis. Again, repair enzymes exist to deal with the oxidative damage in a living cell, but such enzymes would be inactive in fossilized or preserved material. There are no estimates for the half-life of DNA due to oxidation. Other small molecules exist in cells that can cause damage to DNA. One of the best characterized is *S*-adenosylmethionine (SAM). This molecule causes the methylation of nucleic acids, and the activity of the molecule is analogous to a simple alkylating reaction. The main active sites of SAM are ring nitrogens and purine residues. The major products of such methylation are 7-methylguanine and 3-methyladenine. 3-Methyladenine is efficiently repaired by cellular enzymes while 7-methylguanine is not. The latter would be expected to permanently damage DNA. Estimates of the frequency of DNA methylation are on the order of 600 events per day per human cell. All these methods of DNA damage add up to the extrapolation that the half-life of DNA in fossilized material places a theoretical limit on the age of material that should yield DNA long enough to be retrieved in ancient DNA studies (Fig. 1). This limit, estimated by Lindahl at around 30 000 years, is based on extrapolations from experiments in which DNA was manipulated in aqueous solution and at specific pH and temperature values. Many of the fossilization processes discussed in this article are unique in that aqueous conditions are precluded and oxygen is excluded from the specimen at very early stages of preservation (as in amberization).

3
Studies in Molecular Paleontology

3.1
Microscopy Studies

The gross molecular structure of certain cellular organelles has been examined in several fossils. These studies are accomplished by thin sectioning of rocks containing putative microorganisms. The thin sections are then mounted on slides and observed under microscopy. Perhaps the oldest example is the discovery of bacterial filaments from 3.5-billion-year-old formations in western Australia that resemble the filaments from extant cyanobacteria. Other interesting findings from the study of ancient molecular-level structures are the presence of nuclear

membranes in billion-year-old fossils and the presence of colonial algal characteristics in microfossils from the gunflint chert in Michigan. Microscopic examination of amber-preserved fossils has revealed molecular-level information for these types of fossils. Transmission electron microscopy of amber-encased insects discloses astonishing detail at the cellular level. Nuclear membranes, endoplasmic reticula, and ribosomes are all visible in these ancient materials. In addition, chromatin can be detected in these micrographs. Scanning electron microscopy of amber-preserved insects also provides information at the molecular level, although the resolution is much lower.

3.2 Chemical and Amino Acid Studies

Studies of chemical fossils involve the characterization of biomarkers from a variety of microorganisms. Such biomarkers as pentacyclic triterpenoids, hopanes, sterols, pigment derivatives, and acyclic isoprenoids serve as signatures for unique fossil molecules and sediments. Isotopic composition of these biomarkers is a characteristic that is used to determine signature. For instance, *n*-alkanes can have even or odd numbers of carbon atoms. Even-number long-chain *n*-alkanes indicate an origin from plant waxes or algae. Odd-number *n*-alkanes indicate an environment high in salinity. An immediate application of this approach is to the petroleum industry, since *n*-alkanes and other biomarkers are the major components of petroleum. Abelson first showed in the 1950s that amino acids could be isolated from fossilized material. The fossils included representatives of mollusks of various ages, as well as dinosaurs, fish, and mammals from the Phanerozoic.

3.3 Protein and Nucleic Acid Studies

A few studies have reported the structural analysis of proteins from mineralized fossils. One of the earlier reports on recovery of proteins from fossils was the isolation of 80-million-year-old shell proteins from fossil mollusks. Although sequence information was not obtained from this material, the existence of intact proteins in these fossil shells was demonstrated by assaying the isolates on protein gels. Obtaining the actual sequences of fossil proteins is extremely difficult because a relatively large amount of starting material is needed for sequencing, and the amount of protein material in fossils is small. Despite this limitation, the N-terminal 15 amino acids from a small calcium binding protein has been sequenced from fossil oyster shells from the Holocene, Miocene, Cretaceous, and Jurassic epochs. The isolation and characterization of proteins and nucleic acids from ancient tissues for use in phylogenetic studies began with the pioneering work in Allan Wilson's lab at the University of California at Berkeley. Wilson and his colleagues, most notably Russel Higuchi, Ellen Prager, and Svante Pääbo worked on a variety of ancient tissue sources. Jerold Lowenstein, at the University of California at San Francisco, used the immunodiffusion and RIA techniques to examine the serum albumin of several extinct organisms. These techniques result in the establishment of immunological distances between taxa that can be used to infer relationships among organisms by means of distance algorithms. The organisms examined in these early studies were mastodon (*Mammut americanum*), woolly mammoth (*Mammuthus primigenius*), Steller's sea cow (*Hydrodamalis gigas*), Tasmanian wolf (*Thylacinus*

cynocephalus), and quagga (*Equus quagga*). The first report of DNA isolated and characterized from ancient tissue appeared in 1984 and concerned the isolation and cloning of DNA from the quagga. This pioneering study reported the isolation and characterization of a short fragment from the mitochondrial cytochrome *b* gene for this extinct mammal. DNA was isolated from a museum-preserved skin of a quagga that had been collected in the nineteenth century. The isolated DNA was cloned into a λ-vector and isolated by filter lift and hybridization techniques. Comparison of the DNA sequences from the quagga with sequences from other equids in a phylogenetic analysis revealed the close relatedness of the extinct quagga and Burchell's zebra. Publications followed concerning the isolation and characterization of nucleic acids from several animals such as the woolly mammoth, saber-toothed tiger, moa, Bronze Age rabbit, giant sloth, and marsupial wolf to name a few. One of the more interesting cases of phylogenetic inference obtained from ancient tissue sources is that of the marsupial wolf *Thylacinus*. The phylogenetic placement of this extinct marsupial species was determined using data from both immunoprecipitation and DNA sequencing studies. On the basis of morphological evidence (the remarkable similarity of dental and skeletal characters), some systematists have argued that this Australian genus is most closely related to another extinct group of South American carnivorous marsupials called the *borhyaenids*. Other systematists argue, that *Thylacinus* is most closely related to other Australian carnivorous marsupials (dasyurids). In an early study, Lowenstein and colleagues used immunoprecipitation RIA of serum albumin to demonstrate a close affinity of *Thylacinus* with the dasyurids, indicating that the Australian taxa were a monophyletic group and that the South American hypothesis was incorrect. Thomas and colleagues examined the DNA isolated from museum skins of *Thylacinus* for 219 bases of the mitochondrial cytochrome *b* gene and came to the same conclusion. More recently, much older material has been examined. The first study to break the million-year mark was one concerning the isolation and characterization of chloroplast DNA from fossilized magnolia leaves (17 million years old). This study approached the question of the relationship of the extinct magnolia species *Magnolia latahensis* to other closely related plants. Golenberg and colleagues used fossils from the Clarkia beds of Idaho as a source for *M. latahensis*. By means of polymerase chain reaction (PCR) techniques, they obtained an 820-bp long fragment from these ancient fossil plants and compared the sequences to several other plant species. The tree obtained from these analyses indicated that the extant species *Magnolia macrophyla* is the closest relative of *M. latahensis*. The isolation and characterization of DNA from Dominican amber-preserved insects, bacteria, and plants (30 million years old) and Lebanese amber-preserved insects (120 million years old) are examples of increase, by several orders of magnitude, of the limits of the age of ancient DNAs. Attempts to isolate DNA from Baltic amber (60–80 million years old), 80-million-year-old fossilized bone, 200-million-year-old fish fossils, and 400-million-year-old marine invertebrates have also been reported. A major challenge to the success reported in amber DNA studies has come from the work of Austin and colleagues. In a series of carefully planned and executed experiments, authentic ancient nucleic acids could not be isolated from several Dominican amber-preserved

specimens. The inability to isolate authentic ancient DNA from these specimens has curtailed the search for ancient DNA in these exquisitely preserved specimens and instead has focused the ancient DNA field on more recent specimens of age no greater than 100 000 years.

3.4 Molecular Archaeology: Humans and Plants

The primary source for most of the studies in ancient human DNA has consisted of bones or remains preserved in wet bogs, and natural and artificial mummies. Several studies have characterized DNA isolated from bone ranging from tens of years to thousands of years old (Table 3). Egyptian mummies and Amerindian populations were the initial major subjects of human ancient DNA studies. More recently, European and South Pacific populations have gained some attention from anthropologists studying ancient remains. Plant remains on the order of hundreds to thousands of years old have been examined. Examples of plant studies from archaeological studies concern the determination of patterns of domestication of certain cultivated plants such as maize and wheat.

3.5 Utility of Ancient DNA

Ancient DNA studies can be very useful in many aspects of modern biology. Systematists offer perhaps the best example of how these data can be useful. An amber termite study provides a useful example of the importance of nucleic acid information from fossils. Information on nearly 400 bases of the small ribosomal subunit (18S rDNA) was collected for a number of termites and their close relatives: mantids and cockroaches, and several outgroups. When a phylogenetic analysis using only the extant organisms is performed, the position

Tab. 3 Examples showing specimen ages of ancient DNA studies of humans.

Material extracted	*Locale*	*Age of specimen [years before present]*
Human mummies	Egypt	5000
	Andean area	6000
	Southwestern United States	2500
	Aleutian Islands	1400
	Australia	200
	Japan	900
Human bones	Oceanic and Amerindian peoples	3000
	Neanderthal	29 000
	Cro-Magnon	24 000
Human brains	Florida bogs	8000
Human parasites	*Mycobacterium tuberculosis* isolated from human mummies	2000–4000
	Yersinia pestis isolated from teeth of bubonic plague victims	400
	Clostridium from Andean mummy	1000
	Trypanosoma cruzi from Chilean mummy	4000

of cockroaches in the phylogenetic tree is ambiguous. When the extinct amber termite sequences are added to the analysis, however, the tree becomes resolved with respect to the placement of the cockroach. This result supports the contention, familiar to paleontologists, that fossil information is absolutely essential to an understanding of phylogeny in many groups. Two other examples involve the use of ancient DNA information to calibrate molecular clocks and the use of ancient DNA in population biology and conservation. Information about the sequences of extinct organisms is essential in attempts to more accurately determine absolute rates of divergence. If a fossil can be accurately dated and sequences from it can be directly compared to sequences from living organisms, more accurate rates for molecular clock estimates can be obtained. Population-level studies have already demonstrated the value of ancient DNA sequences in population, genetic, and taxonomic studies of wolves, tiger beetles, whales, and prairie chickens, to name a few. The ability to obtain information from extinct taxa and populations is essential in assessing relatedness among endangered species. Information about past genetic diversity has the potential to inform present-day conservation management decisions by providing context for biodiversity estimates and for assessing extinction risk. This information can also shed light on evolutionary processes (organismal and molecular) as well as human cultural practices and impacts.

4 Future of Ancient DNA Research: Authentication

The pioneering work of Higuchi and other members of the Wilson lab demonstrated that it was possible to obtain molecular information from long dead (and in some cases extinct) organisms. This possibility stimulated a field of research and the advent of PCR allowed for a dramatic expansion in the field. Early work focused on attempts to isolate DNA from various organisms, tissue types, and ages of specimens. For practical reasons, many studies relied on the use of high copy number mitochondrial gene regions; however, the information content of mtDNA is limited for studies addressing deep evolutionary questions, and more recent work has shown that it is possible to recover high copy nuclear gene regions such as microsatellites as well as single copy nuclear gene regions from ancient specimens. Ancient DNA research can be thought of as progressing along two nonexclusive paths. One is the application and refinement of ancient DNA extraction techniques in order to address a wide range of systematic, evolutionary, archaeological, and conservation biology questions. The other has focused on gaining an understanding of the molecules themselves by exploring questions such as what are the postmortem processes that degrade DNA, what are the theoretical temporal limits to DNA preservation and what preservation conditions are likely to protect DNA. These types of questions are informed by research in areas such as molecular biology, biochemistry, taphonomy, and forensics.

Given the degraded nature of ancient DNA, one question will remain: how reliable are the data obtained? Much of the recent work in ancient DNA research has focused on establishing means of authenticating ancient DNA sequences. One factor that bears on whether the data are reliable is the development and use of standardized procedures that prevent contamination of extracts with

modern (undergraded) DNA or PCR products and the monitoring of extracts for potential contamination. Several technical precautions are taken in the DNA isolation and PCR amplification stages.

1. Physical separation of labs (and equipment and supplies) where ancient DNA extractions are performed from labs where modern DNA extractions and PCR amplifications occur in order to minimize the potential for contamination of the ancient extract with high quality DNA or PCR product carryover; both of which could overwhelm a PCR of the ancient extract and lead to spurious results.
2. The use of disposable positive displacement pipette tips or plugged, coated pipette tips in all manipulations of DNA, buffers, and enzymes, as well as the use of bleach and UV irradiation of lab, equipment, and reagents.
3. Every PCR experiment involving ancient DNA should include positive and negative controls, run side by side with the experimental reactions to ensure the accuracy of the ancient DNA reaction. When attempting to amplify ancient tissue sources, a portion of the rock (in the case of mineralized fossils) or, in the case of amber, a portion of the amber that surrounds the fossil, should be treated as control material. The occurrence of PCR product from rock or amber without a fossil should be treated as information that the PCR reaction is faulty.
4. Direct and independent corroboration of results from one laboratory should be undertaken in other unrelated laboratories. The characterization of ancient nucleic acids currently relies on the polymerase chain reaction. Two problems specific to the PCR must be considered when examining ancient DNA. Since the *Taq* polymerase used in most PCR reactions preferentially inserts dATP into damaged regions of template DNA, ancient DNA sequences must be scrutinized for the unusual occurrence or frequency of deoxyadenines in amplified sequences. This is especially problematic when the starting template concentration is very low. Since errors introduced in early cycles of the PCR can become fixed, replicate PCR reactions should be performed to monitor sequence variation. The second problem concerns the ability of the PCR reaction to form chimeric molecules via PCR jumping, which occurs when damaged template DNA is degraded to sizes having only one of the priming sites present on the template, the other having been separated by damage. In these cases, the short templates can serve as primers on other pieces of template DNA, and *jumping* occurs across the damaged ends of the original templates. This process results in PCR products from template DNA that sometimes differ in size from the intended product. In addition, if some outside contaminant DNA is present in the PCR reaction, it is possible for a jump to occur from the intended target template to the contaminant. This scenario would produce a chimeric PCR product with sequences from the intended target on one end of the product and sequences from the contaminant on the other. Replication of PCR reactions, cloning of PCR products and replication of extractions can reveal these types of PCR-related problems.
5. Negative results should also be published, to let researchers know what has and what has not been attempted. The weight of the negative results can then

be used to assess the validity of any study that reports success at isolating ancient DNA. Reproducibility of results is a key aspect of reliability assessment. This is problematic for ancient DNA studies for which specimens are rare or unique, and in cases where even microhabitat-level variation in preservation conditions within a site can result in differences in the ability to recover DNA from contemporaneously buried specimens. Information on success rates for ancient DNA recovery from specimens of various ages and preservation conditions can also aid in deciding whether or not to undertake a study.

Another factor affecting whether the data are thought to be reliable is consideration of the likelihood of recovering authentic DNA from a given specimen. More detailed and sophisticated biochemical and chemical analysis of ancient tissues needs to be performed. Involvement of biochemists and chemists in the ancient DNA field to examine the nucleic acid content of ancient materials would be a positive move in this direction. A clearer yet incomplete picture is emerging of the factors that contribute to the postmortem preservation/degradation of DNA. Degradation of DNA over time does not appear to be a linear relationship. Studies have shown that the greater proportion of DNA damage occurs immediately following death and the rate of damage may decrease after that. Studies of contemporaneously buried humans in the same gravesite showed varying amounts of DNA recovered from bones, suggesting that microhabitat-level variation in taphonomic conditions can influence the effect of age on DNA recovery. Studies continue to explore the limits of age, starting materials, and preservation conditions that will yield recoverable DNA in an attempt to arrive at some general indicators of the likelihood of DNA recovery. Many studies continue to raise the upper limit of the age of specimens thought likely to yield authentic DNA (Table 3); however, extreme age of the specimens would suggest DNA recovery is unlikely. On the basis of detailed biochemical analyses of DNA degradation, Lindahl has expressed skepticism about the claims of several researchers on the isolation of DNA from materials older than 30 000 years. Those experiments were done in aqueous solution. Preservation conditions such as desiccation, cold temperature, and high salt may slow the degradation on DNA and allow for recovery of authentic DNA from specimens older than predicted on the basis of studies in aqueous solution. The presence of amino acids and extent of racemization have been used as proxies for indicating whether DNA recovery is likely. While there may be different factors affecting the preservation of proteins and DNA such as the protection of DNA sequestered in bones, teeth or amber, the continued presence of one macromolecule supports the possibility of recovery of another. An exploration of the extent of racemization has been suggested as a prerequisite before attempting ancient DNA extractions.

There is still much research to be done if general principles regarding the likelihood of DNA recovery are to be established. Another, perhaps the most important, factor affecting whether the data are thought to be reliable involves authentication of the resulting sequences. The verification procedures discussed above are indirect methods that minimize and monitor contamination, or infer the likelihood of authentic DNA recovery based on proxies such as age, condition, and the survival of other biomolecules. Detailed phylogenetic analyses provide a direct method of

authentication by identifying whether the resulting ancient DNA sequences are from the organism of interest and not the result of contamination or pseudogene amplification. The discovery of a genealogical relationship of DNA sequences from ancient sources with an extant, close relative is usually taken as verification of authenticity. Consequently, it is necessary to have as many exemplars or taxa as possible available for the phylogenetic analysis. The claim of the isolation and characterization of dinosaur DNA from mineralized fossils was open to question on the basis of these points concerning phylogenetic analysis. These studies highlight potential problems for ancient DNA work using mitochondrial sequences: (1) The presence of contaminating human sequences even in cases where standard ancient DNA lab precautions are observed. Research on organisms other than humans can minimize the impact of this potential problem through the use of species-specific primers in PCRs and by performing phylogenetic analyses on the resulting sequences to confirm that the study organism falls within an appropriate phylogenetic bracket. (2) The presence of copies of mitochondrial gene regions inserted into the nuclear genome. The dinosaur DNA claims and rebuttals showed that not only is human mitochondrial DNA contamination a problem, but that nuclear copies of human mitochondrial DNA can also be recovered. Comparisons of sequences based on Blast similarity scores alone may not be sufficient to rule out contamination owing to the potential for recovering nuclear insertions of mitochondrial sequences. These sequences may have accumulated additional substitutions since their insertion into the nuclear genome and might falsely be thought of as being sufficiently different from human DNA as to have come from the study organism. In fact, phylogenetic methods were used to disprove the authenticity of the dinosaur DNA claims.

Keywords

Chimera
An individual organism composed of a mixed population of parthenogenetic and normally fertilized cells.

Genomic Imprinting
The differential expression of gene alleles, dependent on their parent of origin.

Parthenogenesis
The development of a new individual organism from an unfertilized ovum (an activated egg).

Parthenote
An embryo created by parthenogenesis.

Teratoma
A tumor composed of a variety of mixed tissues derived from two or more germ layers in normal embryonic development.

Uniparental Disomy
The inheritance of a diploid genome from a single diploid parent (the result of parthenogenesis).

One of the most exciting and contentious issues in biomedical science today is the potential use of stem cells as a therapeutic intervention for a wide range of diseases with pathologies that involve cellular destruction. Stem cell therapy is currently practiced, or under active research, to repair the effects of neuromuscular degeneration, autoimmune response, ischemic attack, malignant carcinoma, congenital defects, metabolic disorders, and alcohol-related pathologies. When stimulated in a proliferative environment, stem cells may also provide the raw material for large-scale *ex vivo* tissue regeneration. There are several sources of human stem cells for laboratory culture, but the primary source of pluripotent human embryonic stem cells is the inner cell mass of *in vitro* fertilized embryos. Despite the potential rewards to medicine, experimentation using cells from viable human fetuses has triggered global political and ethical controversy that has slowed down the pace of research. An alternative source of human embryonic stem cells that circumvents some of these issues would significantly enhance research in this area. Parthenogenetically derived stem cells may represent such a resource. Parthenogenesis involves activation of the oocyte without sperm, and produces a nonviable blastocyst. That is, the activated egg develops to the blastocyst (and so can be used to generate stem cells), but it will not produce a viable pregnancy in mammals. The unique genesis of the embryo, and its arrested development at blastocyst, may afford sufficient moral and political latitude to enable its acceptance

as an experimental entity. Research is ongoing to assess the genetic and phenotypic similarity of parthenogenetic stem cells (PSCs) to other stem cell types from mammalian models and to human stem cells derived from fertilized embryos.

1 Background

1.1 A Brief History of Parthenogenesis Research

Parthenogenesis refers to ''the production of an embryo from a female gamete without the concurrence of a male gamete, and with or without eventual development into an adult.'' Parthenogenesis – Greek for virgin birth – is a common form of reproduction for insects such as aphids, flies, ants, and honeybees, but is also known to occur in vertebrates, including lizards, snakes, fish, birds, reptiles, and amphibians. Aristotle might have been one of the first to have recognized this form of reproduction, in fish and bees, as noted in his *Generation of Animals* (340 B.C.), but it was not until 1695 that van Leeuwenhoek documented this form of reproduction in aphids. Charles Bonnet described cyclical parthenogenesis in *Contemplation de la Nature* (1740), followed by Dzierzon's observation 100 years later that drone bees are derived from unfertilized eggs (1845). The term parthenogenesis was first used by Richard Owen in 1849. The first demonstration of *in vitro* artificially stimulated parthenogenesis was made by Jacques Loeb, who was able to activate oocytes from sea urchins and frogs by pricking them with a needle or by changing the ambient salt concentration. In the 1950s, parthenogenesis was classified into subtypes according to the sex of the resulting offspring. Arrhenotoky is parthogenesis where unfertilized ova produce males, while fertilized ova lead to females, as for example in ant and honeybee colonies; in thelytoky, the unfertilized ova become females and in deuterotoky, they may become offspring of either sex. Pincus demonstrated parthenogenetic activation of mammalian eggs in 1939, using temperature and chemical stimuli. To date, parthenogenetic activation of eggs has been accomplished in most mammals, including mice, goats, cows, monkeys, and humans. Plachot et al. were able to identify human parthenogenetic activation events by examining 800 human oocytes. They showed that 12 were spontaneously parthenogenetically activated, and of these, four had undergone normal cleavage. Although there have been no reports of naturally occurring human parthenotes, a human parthenogenetic chimera was recently recognized. The juvenile patient presented as developmentally delayed, with apparent sex reversal, and entirely parthenogenetic blood leukocytes. This finding confirmed the viability of chimeras in higher mammals, as suggested by successful laboratory experiments in mice over the previous two decades (as described in later sections).

1.2 Mammalian Parthenogenesis

There is no confirmed example of natural mammalian parthenogenetic reproduction, but mammalian oocytes can be artificially induced to undergo parthenogenesis *in vitro* by a two-step protocol involving

electroporation and/or treatment with a chemical agent (ionomycin, ethanol, or inositol 1,4,5-triphosphate) to elevate transient Ca^{2+} levels, followed by application of an inhibitor of protein synthesis (cycloheximide) or protein phosphorylation (6-dimethylaminopurine). Success rates and developmental survival time appear to be organism dependent. Mouse parthenotes are capable of developing past postimplantation stages *in vivo*; pig parthenotes have developed up to postactivation day 29 (limb bud stage, past the early heart beating stage); rabbit parthenotes until day 10 to 11, while primates (*Callithrix jacchus*) have only been shown to implant. The reason for this arrested development is believed to be due to genomic imprinting. In fertilized zygotes, maternal and paternal haploid genomes are epigenetically distinct, and both sets are required for successful development. That is, metastable chromosome modifications in the form of methylation, for example, exhibit unique patterns in sperm versus eggs. As a result, they carry unique patterns of gene expression into the embryo. Since all genetic material in parthenotes are of maternal origin, the paternal imprinting component is absent and this prevents proper development of extraembryonic placental tissues (from the trophectoderm) whose expression is regulated by the male genome. In most mammals, (including primates), just prior to ovulation, oocytes are arrested at the metaphase II stage. Cytogenetic microscopy shows the presence of a $2n$ polar body under the zona pellucida and a $2n$ protonucleus in the cytoplasm. After chemical activation to mimic the effects of sperm penetration on changes in cellular Ca^{2+} gradient, the cell does not complete meiosis II. Instead, the second polar body is never extruded, resulting in a diploid protonucleus derived from two sets of sister chromatids. These chromatids then begin to divide mitotically. On balance, then, the parthenote is related to the maternal oocyte by uniparental disomy (Fig. 1).

1.3 Genomic Imprinting

Genomic imprinting is an epigenetic regulatory process that imposes a parent-of-origin control over gene allele expression according to a dynamic program that is dependent on the stage of development and tissue type. A memory of the parental source of each disomic copy of imprinted genes in the genome is preserved, and this is coupled with a mechanism to effect mono-allelic differential expression of the gene copies based on the parent of origin, such as the paternally expressed gene, insulin-like growth factor 2 (IGF2). The time and tissue variability of this process is evident, even as early as oogenesis. The primary mechanism for imprinting is methylation of cytosine residues in DNA CpG di-nucleotides, but histone modifications such as acetylation and methylation cooperate in chromatin modification, reinforcing local genome silencing. It is believed that as many as 200 genes are imprinted in humans, although only about 50 imprinted genes have been identified in mice (with some conservation in humans). The evolutionary reason for the development of imprinting is not clear, but a number of theories have been posited. The ''Conflict Theory'' is one of the more popular and enduring explanations of why genes are imprinted. Empirically, genes that are paternally expressed are often those genes involved in fetal growth, while genes that are maternally expressed restrict growth. In the population genetic theory, the resource burden for carrying a fetus rests disproportionately on females

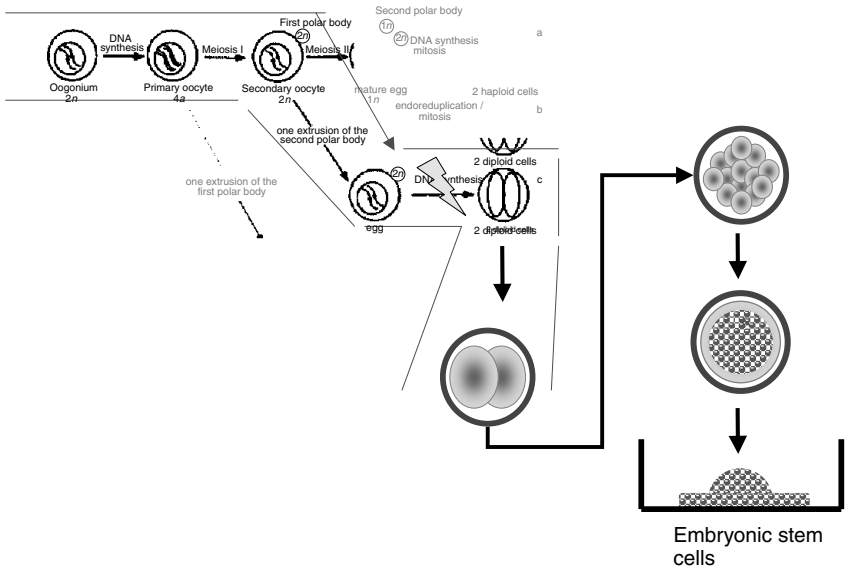

Fig. 1 The process by which stem cells are derived from parthenogenesis. An oocyte is arrested at Metaphase I, and is the artificially activated, bypassing meiosis II. The resulting diploid cells begin to mitotically divide to a morula, and further develop to a blastocyst. At this point, however, the blastocyst fails to form a functional placenta *in vivo*. The inner cell mass (ICM) is then harvested and plated and produces cultured stem cells.

of a species in eutherians (placental mammals) and metatherians (marsupials), and female mammals are known or presumed to be promiscuous. Hence, by carrying fetuses from different fathers, paternal evolutionary drive would seek to maximize resource benefits for his fetus. The counterpoint is that the mother is placed at risk, being drained of much needed nutrients and potentially carrying oversized fetuses; hence, she benefits from rationing the amount of her resources that a fetus can extract. Evidence from seed development reinforces the notion of an intragenomic parental conflict, whereby imprinting intercedes to differentially balance the selfish interests of each sex's genome during the development of the progeny.

It is believed that the parthenotes are not capable of developing to term because they fail to develop the necessary extraembryonic tissues – trophectoderm and primitive endoderm. In contrast, androgenotes (created by the fusion of two sperm nuclei, and of purely paternal origin) develop into a structure consisting of a trophoblast and yolk sac regulated by the male genome. These structures resemble hydatidiform moles (trophoblastic tissue only), which are formed when sperm fertilizes an enucleated egg.

1.4 Human Ovarian Teratomas

In the absence of natural primate parthenotes, human ovarian teratomas may represent one of the few clinical correlates available, albeit as a result of a different (oncogenic) transformation. There is controversy about the histogenesis of teratomas, with apparent subgroups based on gonadal versus extragonadal

site, and maturity of the tumor. Ovarian teratomas represent 10 to 15% of all ovarian tumors, and result from abnormal development of a primary oocyte. Most mature ovarian teratomas (dermoid cystic type predominantly) appear to be 46, XX diploid with a Barr body present, and are believed to be genetically equivalent to parthenotes. They may arise from tumorigenic events at meiosis I and/or II, genome reduplication in a mature ovum, or fusion of two ova, with clinical and genetic evidence to support all of these modes. Mature cystic teratomas are typically composed of adult-type tissues usually representing all three germ layers, including teeth, bone, cartilage, adipose, thyroid, and soft brain tissue. Rarely seen developed organs and tissues such as bowel, appendix, skull, vertebrae, limb buds, external genitalia, pancreas, prostate gland, and eyes will be observed. Ectodermal elements such as skin and its appendages predominate, but neuroectodermal components are also present. These teratomas may occasionally contain foci of immature or fetal tissues, and present with a complex mix of heterogeneous tumors. In contrast, the much rarer immature ovarian teratomas are more likely to have abnormal karyotypes reflecting the genome instability associated with malignant cells, and have variable percentages of immature embryonic-like tissues, together with mature components. Most of the immature tissues are neuroectodermal in this case, and their predominance directly reflects the histological grading of these cancers. The common form of treatment for immature teratomas consists of chemotherapy that not only kills the rapidly dividing cells but also induces a proportion of them to differentiate. The importance of this observation cannot be overstated; chemotherapy generally limits its neoplastic growth by blocking the cell cycle, and its effects are similar to the differentiation induced in *in vitro* cultured parthenogenetic stem cells (PSCs) by the removal of growth factors, as described below. In very rare cases, pluripotent fetiform ovarian teratomas can organize differentiated tissues into a recognizable, but malformed, human fetus or homunculus, thereby showing that pseudonormal programmed development is possible from purely maternal tissues.

The relationship between the etiology and development of the different subgroups of ovarian teratomas and PSCs is not well understood, but there are obvious parallels worthy of further study. In mature ovarian teratomas, the benign nature of the tumor, the observation of a normal diploid karyotype, the involvement of meiotic failure at meiosis II, and the manifest pluripotency of the transformed oocytes have obvious analogy with PSCs. Immature ovarian teratomas, however, recapitulate the tendency of PSCs to commit to a neuronal lineage and the effect of withdrawal from the neoplastic cell cycle in promoting differentiation.

2
Parthenogenetic Stem Cells

2.1
Characteristics of Stem Cells

Stem cells are, by definition, cells that have the ability to replicate indefinitely, and can differentiate into multiple cell types. Embryonic stem cells are pluripotent and have the ability to become most, if not all, cell types in an organism. In contrast, adult stem cells have reduced plasticity, and are usually uni- or, at best, multipotent. They

are also more sensitive to *in vitro* culture conditions, and have shorter survival times than embryonic stem (ES) cells. Currently, there are several sources of stem cells: from *in vitro* fertilization, somatic cell nuclear transfer (cloning technologies), adult tissues, cord blood and germ cells.

2.2 Primate Parthenogenetic Stem Cell Lines

Our experiments in developing parthenote stem cell lines have used the cynomolgus macaque model (*Macaca fascicularis*). After harvesting oocytes from a female hyperovulating macaque, the cells undergo *in vitro* maturation to reach metaphase II. Eight days following oocyte activation with ionomycin and 6-dimethylaminopyridine, 14% of ova reach blastocyst stage, where they arrest (Fig. 1). Transplantation back to a uterus is unable to continue development at this point. The inner cell mass is isolated using immunosurgery; antibodies are added to bind to the trophectoderm, followed by complement proteins. This procedure destroys the trophectoderm leaving the inner cell mass, which harbors precursors to ES cells. These are transferred to grow on mitotically inactivated mouse feeder cells, to keep the stem cells undifferentiated and replicating (Fig. 1).

The creation of embryonic-like stem cells from oocytes is relatively inefficient. Only two primate (one monkey and the other human) PSC lines have been created, and as far as we are aware, only the cynomolgus macaque PSC line is still in culture. The process, described above, was used to generate a parthenogenetic blastocyst (Fig. 2a) and PSCs (Fig. 2b). A human PSC line was generated from 25 human oocytes, yielding 5 blastocysts, and 1 stem cell line that lasted for 2 passages. The difficulties in generating primate PSC lines are probably due to the complexities of higher-order genomic imprinting. However, when PSCs are differentiated into adult tissues, they appear fully functional. Characterization of the differentiated tissues from PSCs in comparison to analogous tissues derived from normal ES cells awaits further study.

2.3 Characteristics of Nonhuman Primate Parthenogenetic Stem Cells

In spite of the nonviability of nonhuman primate (NHP) parthenotes, the extracted stem cells seem to assume the morphology and functional behavior of human ES cells. Morphologically, PSCs possess a small cytoplasmic/nuclear ratio, numerous and prominent nucleoli, and cytoplasmic lipid bodies. Karyotype analysis reveals that the cells are fully diploid with a $2n = 40 + 2$ macaque chromosome complement. Functionally, NHP PSCs express the enzymes alkaline phosphatase and telomerase, showing a loss of the high telomerase activity two weeks after the initiation of a differentiation protocol; this corresponds to loss of pluripotency. Also, like human ES cells, they express the following traditional embryonic stem cell markers: POU domain, class 5, transcription factor 1 (Oct-4), Stage Specific Embryonic Antigen (SSEA-3/4), as well as Tumor Rejection Antigen (TRA 1-60/1-81); moreover, they are negative for SSEA-1 (present only in mouse ES cells, and not in human or primates ES cells). The NHP PSCs express major histocompatibility Class I and II antigens at levels comparable to normal peripheral blood leukocytes after treatment with Interferon-gamma (IFN-gamma). The treatment did not increase

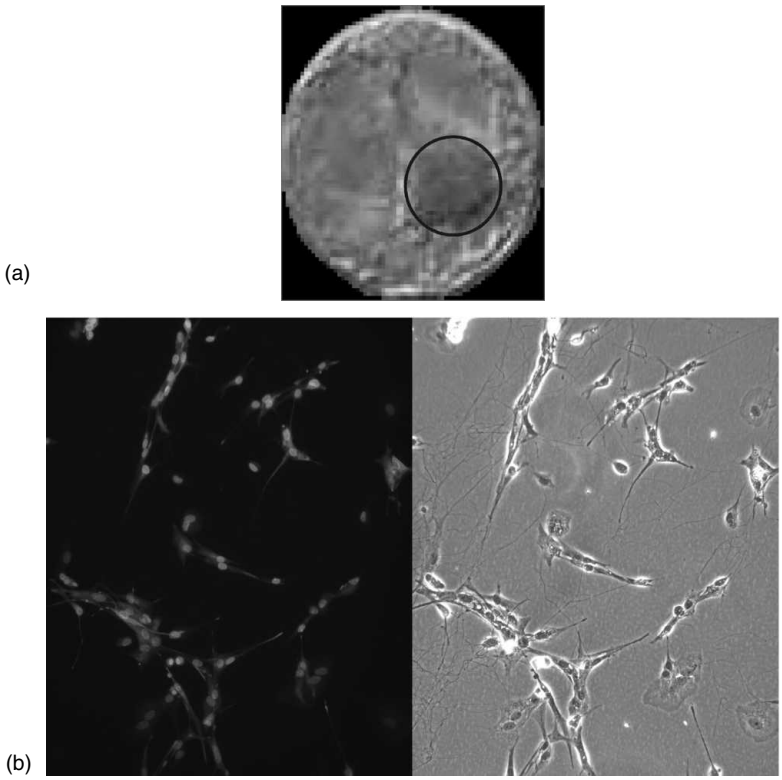

Fig. 2 (a) **Photomicrograph of a parthenogenetically derived blastocyst**. Circled in blue is the inner cell mass (ICM), the source of embryonic-like stem cells. The significance of this is that it is the first primate parthenote in which a stable stem cell line has bee derived. (b) **Photomicrograph of neural precursor cells derived from parthenogenetic stem cells**. Cells stained for nestin (marker for the developing nervous system) (top panel) accompanied by a phase contrast image of all cells (bottom panel). (See color plate p. xxiv.)

class II expression, as one would expect from a non-antigen-presenting cell.

The cells possess the fundamental characteristics of ES cells. They have embryonic-like replicative ability, and have been propagated *in vitro* in an undifferentiated state for up to 14 months. *In vitro* differentiation produces high percentages of dopaminergic and serotoninergic neurons, spontaneously contractile cardiomyocyte-like cells, smooth muscle, beating ciliated epithelia, adipocytes, and several types of epithelial cells. Resulting neurons have been shown to express a voltage-dependent sodium channel, a functional neuronal marker. This multipotency is recapitulated *in vivo*, since injection of NHP PSCs into immunocompromised mice induces formation of teratomas containing derivative tissues from the three germ layers (ectoderm, endoderm, and mesoderm), including cartilage, muscle, bone, neurons, skin, hair follicles, and intestinal epithelia (Fig. 3). The preference of these primate PSCs to differentiate into neuronal tissues has been noted by

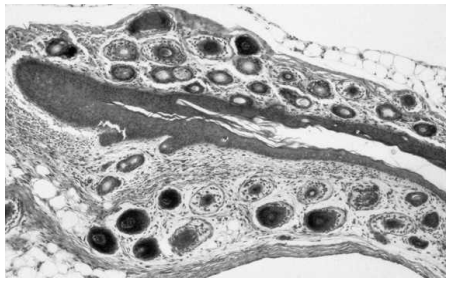

Fig. 3 Teratoma derived from injection into an immunocompromised (SCID) mouse. This H & E stained section demonstrates the *in vivo* differentiation capacity (pluripotency) of parthenogenetically derived stem cells (courtesy of Advanced Cell Technology).

several groups, but the reasons for the underlying preference are not well understood. One possible explanation is that it is a consequence of purely maternal genomic imprinting, and may represent the lack of epigenetic balance that would be conferred by paternally imprinted genes.

2.4 Neuronal Differentiation

In the course of experiments testing differentiation protocols for PSCs, we have identified an intermediate stage along the PSC differentiation trajectory that has unique properties (Fig. 2b). After plating NHP PSCs on a basement membranelike matrix and supplementing the medium with basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF), the cells begin to commit to the neuronal lineage but halt at a transitory state. Cells in this intermediate state stain positive for the neuronal markers nestin and microtubule-associated protein-2. They are negative, however, for choline acetyl transferase, dopamine-beta-hydroxylase, and NeuN, and they do not express ion channels. These Nestin$^+$ precursors are highly replicative (5- to 8-fold increase over a 9-day period), and do not require a feeder layer to grow and remain undifferentiated.

Nestin$^+$ precursor cells can be induced to differentiate to neurons by removing bFGF and EGF, and adding ascorbic acid for a minimum of five days. The resulting differentiated cells represent the neuroepithelial lineage. Almost all of these neurons express TUJ1 (beta-tubulin III), and up to 25% of the TUJ1$^+$ cells coexpress tyrosine-hydroxylase. This latter enzyme marker is considered diagnostic for catecholaminergic neurons (dopamine, norepinephrine, and epinephrine). Furthermore, HPLC analysis of culture media following a depolarizing KCl-buffer identifies the release of the neurotransmitters dopamine and serotonin from the cells. After one week of differentiation, about half of the cells that have a neuronal morphology and begin to express voltage-dependent sodium channels that can be blocked by tetrodotoxin.

3 The Influence of Imprinting on Cellular Growth and Differentiation

3.1 Imprinting and Neuronal Phenotype

There are several developmental disorders that are caused by errors in imprinting, such as Silver–Russell syndrome, Beckwith–Wiedemann syndrome, Angelman's syndrome, and Prader–Willi syndrome. These disorders have extensive associated neurological and behavioral pathologies. Each of these syndromes results from structural disruption of a genome locus

that is subject to maternal or paternal imprinting. Of especial interest here is Prader–Willi Syndrome because it offers an *in vivo*, human clinical model representing only maternal allele(s) in the region of chromosome 15q11-13 (25% have two maternal alleles, 75% have one maternal allele and a deleted paternal allele). It appears that having two maternal 15q11-13 regions is responsible for the neurological and behavior abnormalities. This clinical example correlates with the previous parthenogenetic-chimera studies described below.

By creating mouse chimeras composed of PSCs and biparental ES cells, Keverne and colleagues observed that parthenogenetically derived cells are found predominantly in the neocortex, striatum, and, but not in the hypothalamus, septum, preoptic areas, and brainstem. These studies also showed that parthenogenetic chimeras have brains that are much bigger in size relative to their body weight, although they appear to be anatomically and functionally normal. The area of the brain that is significantly larger, however, is telencephalon. Other chimera studies have shown a restriction of parthenogenetically derived cells in muscle tissue and growth retardation that is proportional to the overall contribution of parthenogenetic cells. However, if the PSCs are cultured for a brief period of time *in vitro*, then used to create chimeras, no pre- or postnatal growth retardation is observed, and higher overall levels of PSCs are detected than in other studies. However, the cells distribute among tissues as per noncultured PSCs. Disruption of imprinting by the *in vitro* culturing step would contribute to this perturbation of cellular distribution.

From an evolutionary perspective, an increase in brain size is correlated with an increase in the complexity of imprinting. For example, the neocortices of prosimians (lower-order primates) are 54% of their total brain weight, while the neocortices of opossums are 22%, and the neocortices of basal insectivores occupy only 13%. This forebrain evolution also correlates with a switch from hormonal dependence to a more cognitive control of behavior. Taken together, these observations suggest that maternal imprinting has an effect on the development and function of the brain. Since the evolution of genetic imprinting coincides with an exponential growth of brain to body size, has evolution coupled its need for genetic diversity to forebrain evolution? Could maternal imprinting explain why PSCs have a tendency to form neurons?

3.2 Imprinting and Parthenogenesis

After the creation of PSCs, the cells and their tissue derivatives seem to assume the traditional phenotype and characteristics of the biparental stem cells. Since imprinting is temporal and tissue specific, and given that many imprinted genes are involved in fetal growth, one would expect some unusual growth characteristics of PSCs. This is true in the very early stages. For example, we have noticed that human PSCs do not spread out and grow like biparental stem cell colonies. Although the inner cell mass attaches to the mouse feeder cells, the cells do not begin dividing like true ES cells. The cell masses have survived in culture for up to several weeks but eventually die. However, in differentiating monkey PSCs into adult tissues, there is evidence that they appear fully functional.

It appears that lack of paternal imprinting does not affect cell phenotype, behavior, and function, once the inner cell

mass attaches to the feeder layer. The dangers of abnormal imprinting appear to be less severe than once thought. Confirming our observations, Szabo and coworkers have demonstrated the presence of mRNA from imprinted genes, where expression of mRNA should have been absent. Many of the stringent effects of imprinting are overcome when the oocytes are artificially activated with chemicals or electroporation. Imprinting appears to play a less significant role as a PSC differentiates, as confirmed by the diversity and functionality of cells generated from PSC. Imprinting may still be affecting the behavior of the cells, but it is only having a minor effect on the differentiation potential by altering PSC responses to developmental cues, such as ligands, growth factors, and so on.

In addition to the Conflict Theory, genomic imprinting might be a mechanism by which to prevent spontaneous births (via parthenogenesis). A possible reason why eutherians cannot reproduce parthenogenetically is that their sexual phenotype is determined by genetic dichotomy, while the phenotype of parthenogenetically reproducing species is influenced by environmental or behavior selection pressures. Since the species that commonly reproduce via parthenogenesis have equal-sized sex chromosomes, it makes it much more difficult to maintain genetic diversity. The ability to inactivate the X chromosome demonstrates how the complexity of genetic imprinting correlates with the complexity of the organism. This difference is best demonstrated by the insulin-like growth factor 2 receptor (Igf2r) gene being imprinted in the mouse and not in the humans. Many imprinted genes are differentially expressed in early development (fetal growth and function of the placenta), and then become biallelically expressed in the adult.

4
The Promise of Parthenogenetic Stem Cells

4.1
Parthenogenetic Stem Cell Therapy

The unprecedented research interest in embryonic and adult stem cells lies in their potential to replace diseased cells or regenerate organs that have been lost as a sequela to disease, or through a traumatic event. Research on PSCs is still in its infancy, with much that is poorly understood about the mechanisms underlying the fundamental properties of self-renewal and the cooperative cellular programs that regulate differentiation. It appears *prima facie* that the lack of paternal imprinting does not affect the self-renewal or pluripotency of the stem cells isolated from the inner cell mass of the parthenote, the cells that are matrilineally regulated. The pluripotency of the stem cells could offer therapy options for a variety of diseases, but the tendency of the PSCs to commit to the neuronal lineage under *in vitro* culture conditions suggests that interventions in neurodegenerative disorders such as Alzheimer's and Parkinson's diseases as well as alcohol-induced Wernicke–Korsakoff syndrome might be the most tractable therapy options.

A major advantage of PSCs over ES cells derived from a normally fertilized conceptus is their unique genome inheritance as a result of uniparental disomy, and the implications for immunocompatibility. Heterologous transplantation of adult stem cells, or ES cells derived from an anonymous stem cell line or from cord blood, requires immunological donor/recipient matching. Autologous transplantation using cord blood stem cells requires long-term storage,

is costly, and requires advanced planning. Although meiotic recombination may shuffle the allele combination in the parthenotes, relative to the somatic genome of the maternal parent, PSCs should be highly immunocompatible with the oocyte donor female, and offer a treatment option for women over the period that they retain an ovarian reserve, and the oocytes can be parthenogenetically activated. Alternatively, one could envisage generation and cryogenic storage of PSC from all women of childbearing age. Moreover, androgenote generation – derived from the fusion of two sperm nuclei in an enucleated egg – while currently undeveloped, provides the possibility of creating these types of cells for males.

Finally, as mentioned in the introduction to this chapter, PSCs offer a unique stem cell resource that literally does not require the creation of fertilized and viable embryos for research, nor the destruction of unused embryos from assisted reproductive technology. The hope is that this might abrogate many of the ethical concerns surrounding research on human ES cells and provide the necessary flexibility to allow research to continue. Parthenotes are not free from ethical controversy though, and are viewed by some in society as artificial entities that in some sense represent ''tampering with nature.'' The proof that a human chimera is possible by natural events, and by existing medical practice in the treatment of human ovarian teratomas, has a direct bearing on the complex ethical status of human parthenotes. As discussed above, the spontaneous *in vivo* tumorigenic event creates a similar phenotypic entity for classes of teratomas, as compared with *in vitro* parthenogenetic activation. Since most mature ovarian teratomas appear to be composed of 46, XX diploid chromosomes with Barr Body present, the two cell types can also be argued to be cytogenetically equivalent. Despite their nonviability for development of pregnancies, the idea that parthenotes are artificial is not as axiomatic as might be thought. Furthermore, since there is *de facto* acceptance of experimentation using teratoma tumor tissue and surgical destruction after resection, this lends some legitimacy to experimentation on parthenotes. These contradictions await reconciliation in a comprehensive ethical framework.

4.2 Primate Parthenogenetic Stem Cells are a Unique Tool to Study Epigenetic Regulation

Primate PSCs serve as a unique discovery tool to study the epigenetic mechanisms involved in development and gene expression. The unilineally inherited diploid genome enables the detailed influence of maternal imprinting to be studied in isolation, and by sampling cells from time points along the path of differentiation, and with differing phenotypes, a multidimensional profile of imprinting by time and lineage will be possible. Further comparison with stem cells derived from embryos with a biparental origin will allow the maternal and paternal contributions to be disentangled at these data points, giving insight into their relative influence at different stages of cell maturity and lineage committal.

Keywords

pathogen-associated molecular pattern (PAMP)
Structural motif of a microbial constituent, for example, of a cell wall component or genetic material. These motifs are not really pathogen specific, but occur also on other microorganisms. They are, however, distinct from any motifs encountered in vertebrate hosts. PAMPs are recognized by host cells via pattern-recognition receptors, initiating a cascade of antimicrobial activities.

toll-like receptors (TLR)
A family of pattern-recognition receptors bearing strong homologies to Toll, a protein involved in dorsal-ventral patterning as well as antifungal responses in *Drosophila melanogaster*. TLR ligation results in intracellular signaling cascades that lead to the elaboration of antimicrobially active molecules as well as to the regulation of adaptive responses.

Innate Immunity
All immune responses executed by cells of the innate immune system, that is, granulocytes, monocytes, macrophages, natural killer cells, and mast cells. These responses comprise sensing microbial motifs, activating effector molecules, and alerting specific lymphocytes.

Adaptive Immunity
All immune responses executed by specific antigen-receptors bearing T and B cells. A generally accepted view of adaptive immunity and, in particular, effector T-cell development and function distinguishes between type 1 and type 2 responses. Infection with bacteria, viruses, and fungi, or stimulation of innate immune cells with components thereof, induces type 1 immunity, mediated by T helper 1 (Th1) or T cytolytic 1 (Tc1) cells. In this context, type-1 cytokines (i.e. Interleukin-2, IL-12, IL-15, IFN-γ, IFN-α, and IFN-β) are particularly involved in cell-mediated immunity to intracellular microbes. Cytotoxic T cells can kill infected cells, using perforin and granzymes. In contrast, infections by extracellular pathogens and multicellular parasites, or exposure to allergens, induce type 2 responses. Type-2 cytokines (i.e. Interleukin-4, IL-5, IL-6, IL-10, and IL-13) play a crucial role in promoting humoral immunity and/or immune deviation to a nonprotective response (tolerance).

Cytokines
Polypeptides enabling the communication between cells, mostly of the immune system. Cytokines are involved in the growth, differentiation, survival, and activation of cells bearing specific receptors.

Chemokines
Chemoattractive molecules (polypeptides with positionally conserved cystein residues) that induce migration of chemokine-receptor bearing cells along a gradient toward the site of their production.

Responses of macrophages, dendritic cells, granulocytes, and mast cells constitute the first line of immune defense against infectious agents. These cells have the capacity to recognize and distinguish between physicochemical motifs expressed on microbes and to tailor rapid antimicrobial defenses accordingly. Identification of microbial constituents involves host membrane-bound detectors, called *toll-like receptors*, and intracellular sensors, termed *Nod proteins*. Upon activation, the innate immune system arms a series of effector molecules capable of thwarting the growth or killing invading microorganisms, including oxygen and nitrogen metabolites. Innate immune cells also play a central role in instructing the adaptive immune system as to which type of specific response should develop to optimally combat infectious agents. To this end, innate cells translate the sensed danger or damage wrought by infectious agents into a language understood by specific lymphocytes, including membrane-bound costimulatory molecules and soluble mediators in the form of cytokines and chemokines.

1 Relationship between Innate and Adaptive Immunity

More than 98% of multicellular animal species cannot produce an adaptive immune response to a pathogen. Immunological memory is thus a privilege of a few vertebrate hosts, and its primary purpose is to sterilize primary infection and provide resistance to reinfection with pathogens. However, during the time it takes for clonal expansion of antigen receptor-bearing lymphocytes to occur, the primordial system of innate defense takes care of the host. Individual functions of innate immune cells are not only involved in mitigating the damaging insults of microbial or tumor growth but are also critical in directing the differentiation processes that, following antigen encounter, ultimately lead to T and B effector cells.

Full-fledged adaptive immunity, in turn, is the result of cells of the adaptive immune system calling upon cells of the innate immune system, either to provide professional phagocytes to engulf and destroy pathogens (type 1 immunity) or to release toxic mediators in order to establish environments that are inhospitable to

helminth or arthropod invaders (type 2 immunity). As a consequence, the innate and adaptive immune systems should be viewed as two interdependent parts of a single integrated immune system.

It is the purpose of this chapter (1) to delineate some of the mechanisms that trigger the activation of innate immune cells during infection; (2) to describe some of the engrained effector functions exerted by innate immune cells upon activation; and (3) to summarize the mediators and dissect the major molecular pathways regulating the differentiation of effector functions of adaptive immunity.

2
Functions of Barrier Organs

Infectious organisms first need to gain access to their preferred sites of multiplication by penetrating either the skin or mucosal surfaces in the lung, gut, or urogenital tract. Antimicrobial defenses within these barrier organs are not generally thought of as facets of ''immunity,'' but are certainly innate and highly effective.

The skin provides an impenetrable barrier for most microorganisms as long as there are no erosions owing to injury or insect bites. Secretions from sebaceous glands, slightly acidic pH, and competition from resident members of the ''commensal'' skin flora make it difficult for many infectious agents to take hold. In addition, epidermal cells are a major source of antimicrobial peptides that can kill a variety of bacteria and fungi; in fact, the initial purification of human defensins was first successfully performed from shedded psoriatic skin.

The gut is lined with goblet cells that secrete mucus, which serves as a nutrient to the resident intestinal flora. The normal flora of the large intestine, for example, consists of approximately 10^{14} bacteria comprising more than 500 species, which provide severe competition for potentially invasive pathogens, particularly in terms of nutrient supply and attachment to the gut epithelium. Mucus is also the carrier of a number of antimicrobially active substances, secreted from epithelial cells and Paneth cells located in the crypts of the intestinal villi. These antimicrobial proteins effectively prevent bacterial adhesion and invasion into lower strata of the gut mucosa.

The upper airways are also covered with viscous mucus, which contains high concentrations of lysozyme and lactoferrin, as well as epithelial defensins. This combination of antimicrobials enables initial control of most infectious agents, leaving mucociliary clearance to accomplish further expulsion. The alveoli of the lower respiratory tract are bathed in lung surfactant. Surfactant proteins A, B, C, and D have multiple functions: on the one hand, they can opsonize bacteria and thereby enhance phagocytic uptake, on the other hand, they also modulate overall macrophage functions, thereby regulating excess inflammatory responses.

3
Activation of Innate Immunity: Sensing the Enemy

Once a pathogenic organism has penetrated the mucosal or epithelial barrier systems, defense strategies initiated by cells of the innate immune system take over. These are strategically placed on many mucosal surfaces (e.g. alveolar macrophages in the lung) and are primarily aimed at recognizing foreign structures and eliminating them. Since infectious pathogens

have often evolved to subvert these mechanisms, specialized cells of the innate immune system are also capable of presenting digested antigen to T cells in a context and environment appropriate for optimal effector cell development. Activation of innate immunity to provide this context may be conceptually divided into three stages (Fig. 1): (1) a phase of antigen sensing during which a combination of surface receptors detects the presence of nonself structures on invading microorganisms (''detection phase''); (2) a phase of translating this sensory information into a language understood by the cells of the adaptive immune system, for example, chemokines and cytokines (''transmission phase''); (3) a phase of mobilizing an effector armamentarium, capable of eliminating or at least restricting the multiplication of infectious agents (''effector phase''). This latter phase may proceed, to a limited extent, without the help of the adaptive immune system, but is consistently amplified by it to maximal potency.

3.1 Pathogen-associated Molecular Patterns (PAMPs)

The costimulatory signals required for differentiation of adaptive immune responses are exclusively turned on when cells of the innate defense system interact with pathogen-associated molecular

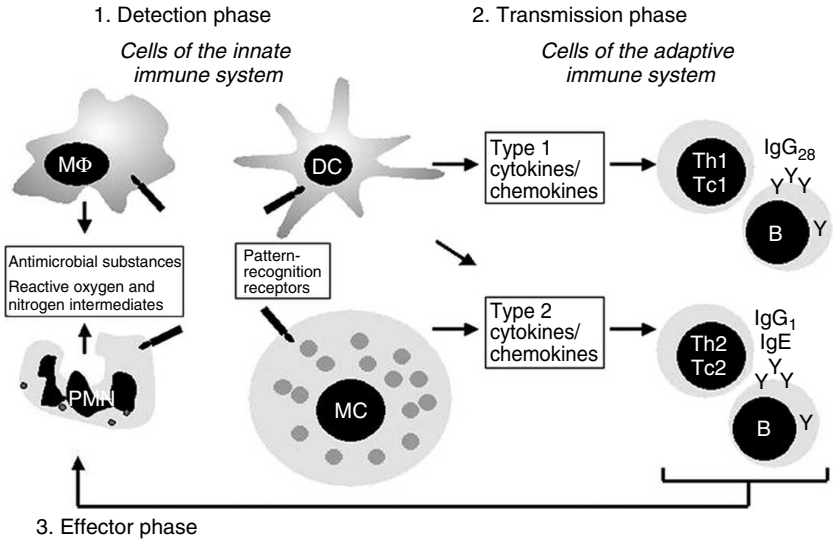

Fig. 1 Overall view of innate immune responses. Cells of the innate immune system (DC = dendritic cells; MC = mast cells) detect the presence of foreign structures, such as pathogen-associated molecular patterns, by surface-expressed pattern-recognition receptors (''detection phase''). Innate immune cells translate this sensory input into a language (cytokines, chemokines) understood by cells of the adaptive immune system, skewing the response into either T helper 1 (Th1)/T cytolytic 1 (Tc1) or Th2/Tc2-type immunity (''transmission phase''). At the same time, ligation of pattern-recognition receptors initiates an antimicrobial program within innate immune cells (''effector phase''). This program is further amplified and complemented by activating cytokines derived from differentiated adaptive immune cells.

patterns (PAMPs, that is, highly conserved structural motifs that are necessary for the survival of microorganisms).

Many pattern-recognition receptors primarily serve the purpose of enhancing phagocytosis. For example, the macrophage mannose receptor (recognizing terminal mannose and fucose residues on microbial cell walls) or the macrophage scavenger receptor (recognizing polyanionic ligands, such as double-stranded RNA, lipopolysaccharide, and lipoteichoic acid) are mainly involved in clearing pathogens from the site of invasion.

Discrimination between different classes of microorganisms, however, is afforded by the toll-like receptors 1 through 11. Since PAMPs have multiple effects on the signals generated by cells of the innate immune system and may therefore be useful as natural adjuvants in driving adaptive responses, they are described here in detail (Table 1). Surveillance mechanisms that sense and respond to microbial compounds in the cytosol are provided by the Nod proteins, a family of nucleotide-binding site, leucine-rich repeat proteins.

Peptidoglycan (*PG*) is a component of all bacterial cells. PG chains consist of alternating β-MurNAc(1 $\rightarrow$ 4)GlcNAc disaccharide units linked via β-(1 $\rightarrow$ 4) glycosidic bonds. Peptide side chains, which are

Tab. 1 Recognition of pathogen structures via surface or intracellular receptors on innate immune cells.

Pattern-recognition receptors on innate immune cells	***Cellular distribution of expression of pattern-recognition receptors***	***Pathogen-associated molecular patterns recognized by pattern-recognition receptors***
TLR1/TLR2	Monocytes, macrophages, DC	Triacylated lipopeptides
TLR2	Monocytes, macrophages, DC	Lipoproteins, lipoteichoic acid, glycolipids, modulin, arabinose-capped lipoarabinomannan, GPI-anchored molecules from parasites
TLR2/TLR6	Monocytes, macrophages, DC	Diacylated lipopeptides; zymosan
TLR3	DC, NK cells	Double-stranded RNA
TLR4	Macrophages, DC, and endothelial cells	Lipopolysaccharide
TLR5	Monocytes, immature DC, NK cells	Flagellin
TLR7 and TLR8	B cells, plasmacytoid precursor DC	Imidazoquinoline derivatives, single-stranded RNA
TLR8	Monocytes, NK and T cells	Imidazoquinoline derivatives, single-stranded RNA
TLR9	B cells, macrophages, NK cells, plasmacytoid precursor DC	Unmethylated CpG-motif oligonucleotides
TLR10	B cells, plasmacytoid precursor DC	Currently unknown
TLR11	Epithelial cells	Uropathogenic bacteria
NOD-1	All cells	D-Glu-mesoDAP
NOD-2	Bone marrow–derived cells	MurNAc-L-Ala-D-isoGLn

attached to the carboxyl group of muramic acid residues, are primarily composed of five amino acids (L-Ala-D-Glu-X-D-Ala-D-Ala, where X stands either for L-Lys or diaminopimelic acid). Certain variations both in peptide and glycan structure exist, depending on the microorganism. A core constituent of PG, muramyl dipeptide (MurNAc-L-Ala-D-isoGln) is recognized by the intracellular sensor protein, NOD2. The minimal structure recognized by NOD1 is the terminal two amino acids in the stem peptide of a peptidoglycan structure mainly found in Gram-negative bacteria: D-Glu-mesoDAP.

Lipopeptides and lipoproteins are components of both Gram-positive and Gram-negative cell walls and may be viewed as functional substituents of PG. A 19-kDa lipoprotein derived from *Mycobacterium tuberculosis* activates cells via TLR2. The diacylated mycoplasma macrophage-activating lipopeptide (MALP-) 2 requires the cooperation of TLR2 and TLR6 to initiate proinflammatory responses, whereas triacylated bacterial lipopeptides require dimerization of TLR2 with TLR1.

Lipoteichoic acid (*LTA*) is an amphiphilic, negatively charged glycolipid found in most Gram-positive bacteria. Appropriate purification of LTA from *Staphylococcus aureus*, or chemical synthesis of LTA, have revealed LTA to be a potent and exclusive TLR2 stimulus. Structural requirements include a lipid anchor and D-Ala substituents, as L-Ala derivatives reduce the activity by a factor of 100.

Lipopolysaccharide (*LPS*) is a major component of the outer membrane of Gram-negative bacteria and is composed of polysaccharides attached to a lipid portion (lipoid A). Lipoid A is responsible for all biological activities ascribed to LPS, and it is the spatial conformation of lipoid A – in part determined by the number and length of acyl chains – that determines biological activity on a given cell type. LPS recognition by TLR4 requires several accessory molecules. LPS is first bound to the LPS-binding protein LBP, which transfers LPS monomers to CD14. How exactly CD14 facilitates LPS recognition is unclear, as is the exact role of MD-2, another component of the LPS-recognition complex. Ultimately, LPS interacts with TLR4 and initiates both MyD88-dependent and -independent intracellular signaling cascades. Some forms of LPS (e.g. from *Porphyromonas gingivitidis* or *Leptospira interrogans*) seem to be recognized by TLR2. The structural requirements for this interaction are not clear, other than that this recognition is greatly enhanced in the presence of TLR1. Uropathogenic *Escherichia coli* contain another, not yet defined structural motif that is capable of activating TLR11 on macrophages and liver, kidney, and bladder epithelial cells.

Flagellin is the protein subunit of bacterial flagella. It is recognized by TLR5, possibly via highly conserved N- and C-terminal ends that form its hydrophobic core. TLR5 is expressed only on the basolateral, but not apical, surface of epithelium. Therefore, flagellin of invading pathogens, but not commensal bacteria, induces intestinal epithelial cells to mount an inflammatory response.

Unmethylated CpG DNA motifs are prevalent in bacterial, but not vertebrate, genomic DNA and are recognized by host cells bearing TLR9. TLR9 is not on the cell surface but is present in vesicles that fuse with lysosomes. Some CpG motifs are very powerful activators of NK cells and induce IFN-α production by DC2 cells; other motifs are potent B-cell activators, triggering cell cycle progression and antibody secretion. Nonspecific activation of innate responses afforded by CpG can increase

resistance in animal models of intracellular infection and sepsis. The ability of CpG to act as a potent adjuvant was confirmed in studies using both model antigens, such as hen egg lysozyme, ovalbumin, as well as tumor antigens and antigens from infectious agents, including hepatitis B, HIV, and influenza virus or *Leishmania major*. In fact, CpG is a stronger Th1-like adjuvant for inducing B- and T-cell responses than the gold standard, Freund's complete adjuvant, as measured by its ability to drive the differentiation of cytolytic T cells and IFN-γ-secreting cells. It should be noted that optimal CpG motifs for activation differ between human beings and mice.

Lipoarabinomannans (*LAMs*) are lipoglycans restricted to the genus *Mycobacterium*. The carbohydrate backbone is comprised of a D-mannan core and a D-arabinan domain. At its reducing end, the mannan core is terminated by a glycosylphosphatidylinositol anchor, while the arabinan domain is capped by either mannosyl (ManLAM) or phosphoinositide residues (PILAM). PILAMs prevalent in rapidly growing mycobacterial species (*M. smegmatis*) activate mammalian cells in a TLR2-dependent manner to secrete TNF and IL-12. In contrast, ManLAM is not an agonist for TLR2. A small mycobacterial glycolipid, phosphatidylinositol dimannoside (PIM) also activates cells in a TLR2-dependent manner.

Double-stranded RNA (*dsRNA*) is produced by most viruses during their infectious cycle. DsRNA induces protein kinase R activation via TLR3. TLR3 is expressed predominantly on myeloid DCs, making them the prime targets for initiating innate responses against viruses. TLR3-deficient mice also showed a reduced response to the viral RNA mimic, polyinosine-polycytidylic acid (poly I:C).

Single-stranded RNA (*ssRNA*), prepared from GU rich sequences in HIV-1 RNA, was found to ligate TLR7 and TLR8. During viral infection, ssRNA possibly reaches the endosome through receptor-mediated uptake of viral particles or by fusion events of budding viruses. Another class of TLR7 and TLR8 ligands is constituted by a series of small synthetic antivirally active molecules, the imidazoquinolines.

Glycosylphosphatidylinositol-anchored molecules (*GPI*) are the predominant antigens present on the plasma membrane of protozoa such as *Trypanosoma cruzi* and *Plasmodium falciparum*. GPI from *T. cruzi* are recognized by TLR2 and potently induce nitric oxide, TNF, and IL-12 in murine macrophages. The PI moiety is mostly composed of unsaturated fatty acids, which are essential for optimal biological activity.

FimH is a subunit protein of type 1 fimbrial adhesins present in many enterobacterial species, for example, *E. coli* or *Salmonella enterica*. It can bind directly to a GPI-anchored receptor present also on the surface of mast cells (CD 48). Ligation of CD 48 by FimH-expressing bacteria results in bacterial uptake into caveolar chambers, promotes bacterial survival inside the cytosol, and has been linked to the release of inflammatory mediators by mast cells.

Heat shock proteins (*HSPs*) are released from necrotic cells during tissue injury or lysis of infected cells, and can form stable complexes with peptides. Some of them, for example, HSP60, can be recognized by TLR4; others, for example, gp96, HSP90, and HSP70, interact with antigen-presenting cells via a common receptor, CD91. HSP-chaperoned peptides enter the macrophage/dendritic cells through CD91 and are processed and presented by the MHC class I and MHC class II

molecules, resulting in the stimulation of CD4 and CD8 T cells. HSP-DC interaction through CD91 leads to maturation of DCs and secretion of an array of proinflammatory cytokines. Immunization of mammals with HSP-peptide complexes elicits potent responses against the HSP-chaperoned peptides.

Parasite-derived glycans and lectins, for example, from *Schistosoma mansoni* eggs or filarial nematodes, trigger responses by TLR-independent mechanisms and are known for their potent induction of Th2 responses. One well-characterized lectin from *S. mansoni* eggs, termed *IPSE*, leads to cross-linking of IgE on basophils, which release IL-4 and IL-13, thus driving a strong Th2 response.

All currently known PAMPs are derived from prokaryotic, fungal, viral, or protozoan pathogens, and it is currently unknown which receptors are required for recognition of ''patterns'' or structural motifs expressed by multicellular eukaryotic parasites or allergens. Whether as yet undefined molecular patterns are at all necessary to skew adaptive immunity toward a type 2 pattern after encounter with these different types of insults remains to be determined. It is possible that a different type of signal, such as the absence of PAMPs – similar to the lack of self-MHC I for NK-cell activation – is a stimulus in itself for triggering type 2 immunity.

3.2 Host Cellular Sensors

At the immunological level, innate defenses rely mostly on granulocytes, mast cells (MC), macrophages, dendritic cells (DC),natural killer (NK), NKT, and $\gamma\delta$T cells. These cells serve as a bridge between PAMPs and antigen-specific cells of the adaptive immunity, translating the sensory input of pattern-recognition receptors into soluble mediators that communicate with T and B cells via specific cytokine/chemokine receptors. Although many cell types contribute in various ways to linking innate and adaptive responses, we shall focus in this chapter – for the purpose of clarity, and because the two prototypic immune responses (type 1 and type 2) are differentially regulated by them – on two pivotally involved cell types, DCs and MCs.

3.2.1 Dendritic Cells

The key cell type, and indeed the most potent type of any antigen-presenting cell, which is able both to sense a foreign insult and to orchestrate the cells of the adaptive immune system, is the dendritic cell. Like other cell types within the immune system, immature DCs are continuously produced from hematopoietic stem cells within the bone marrow. Flt-3 ligand and, to a lesser extent, granulocyte-macrophage colony-stimulating factor (GM-CSF) are the key growth and differentiation factors *in vivo*.

Immature DCs have long been considered ''sentinels'' of the immune system, since they are specialized, relatively long-lived phagocytic cells, which are resident in most tissues where they survey the local environment for pathogens. Pattern-recognition receptors, in particular, TLRs, allow DCs to recognize microbial antigens and mature into highly effective antigen-presenting cells, undergoing changes that enable them to activate pathogen-specific lymphocytes, which they encounter in the lymph nodes.

Maturing DCs lose the ability to take up and process antigen, but they upregulate surface expression of MHC class I and II expression, as well as of costimulatory and adhesion molecules such as CD86, CD80,

CD40, and CD54. Mature DCs express proinflammatory cytokines like IL-6, IL-12, IL-18, IL-23, and IL-27, and are able to detect the expression of cytokines by infected cells, thus integrating different signals of danger. Another consequence of imDC stimulation is the upregulation of CCR7 expression and downregulation of CCR5 expression, which allows DCs to migrate to regional lymph nodes. There, mature DCs prime naive T cells and, depending on the predominating maturation signals, differentially induce Th1 versus Th2 development. Bacterial CpG DNA, double-stranded viral RNA, LPS, as well as CD40 ligand and IFN-γ induce immature DCs to produce IL-12 and promote Th1 immune responses. In contrast, anti-inflammatory molecules such as IL-10, TGF-β, corticosteroids, and prostaglandin E_2 promote Th2 or regulatory T-cell immune responses.

The ability of DCs to prime greatly diverse immune responses is the result of different DC subsets and their unlimited plasticity. In addition to immature DCs, stem cells also give rise to two types of DC precursors (pre-DCs), monocytes (pre-DC1) and plasmacytoid cells (pre-DC2), during hematopoiesis. Functionally, immature DCs and pre-DCs differ since pre-DCs are more directly involved in innate immunity against microbes. Pre-DC1 phagocytose and kill various bacteria and fungi, while pre-DC2s play a major role in the early antiviral innate immune response by producing large amounts of IFN-α/β upon viral infection. Therefore, these cells were also named ''natural interferon–producing cells'' (NIPCs). Unlike other innate immune cells, such as neutrophils, eosinophils, and basophils, which die after performing their functions, pre-DC1 and pre-DC2 differentiate into DCs. When placed in culture with GM-CSF and IL-4, or after bacterial uptake, pre-DC1 differentiate into immature myeloid DCs. Upon CD40 ligand–induced activation, DC1 produce large amounts of IL-12 and prime Th1 and cytotoxic T-cell immune responses. In contrast, pre-DC2 differentiate into immature DC2 in the presence of IL-3 or CD40 ligand, and mature DC2 primarily induce Th2 immune responses. Interestingly, when immature DC2 cells become infected by a virus, they take on the typical morphology of mature DCs and upregulate costimulatory molecules, but acquire the distinct ability to differentiate naïve CD4+ T cells into producers of IFN-γ and IL-10.

3.2.2 Mast Cells

Mast cells (MC) are derived from CD34+ stem cells. They initiate their differentiation in the bone marrow under the influence of stem cell factor and interleukin-3 . Their final maturation takes place in connective tissues.

Within minutes following activation, mast cells extrude granule-associated substances, such as histamine. Within hours, mast-cell activation is followed by *de novo* synthesis of numerous cytokines (TNF-α, Interleukins 1–10, IL-12, IL-13, IL-15, IL-16, IL-18, IL-25, GM-CSF) and chemokines (CCL2-5, CCL8, CCL11, IL-8). Mast cells are long-lived and therefore able to respond repeatedly to the same stimulus.

In addition to their well-established central role in the pathogenesis of allergic disorders, MCs are now also appreciated as key effector cells in the induction of protective immune responses to bacteria. This notion is supported by several independent lines of evidence. MCs are found at the portals of entry of many infectious agents, that is, within mucosal surfaces of the gastrointestinal and respiratory tracts,

or in the skin in close proximity to peripheral nerves and are often associated with blood vessels. MCs are equipped with a large variety and number of receptors to detect bacteria or signs of bacterial infection including toll-like receptors (TLRs), CD48, and complement receptors. Furthermore, genetically MC-deficient animals, such as Kit^{W}/Kit^{W-v} mice, exhibit insufficient host defense responses in various models of bacterial infection, for example, in cecal ligation and puncture-induced acute septic peritonitis. Finally, protection from bacterial infections in mice can be improved by enhancing MC numbers and/or function.

Mast cells may exert many different effects on inflammatory processes: (1) at early stages, mast cells can be activated via TLRs in the peripheral tissues through interaction with microbes; (2) the release of cytokines, such as IL-4 and IL-13, may influence DC maturation, and as a consequence, biases T-cell differentiation to a Th2/Tc2 phenotype; (3) mast cell–derived chemokines may recruit distinct subsets of inflammatory cells to the site amplifying a predominantly type-2 response; (4) activated mast cells can migrate to secondary lymphoid organs, where they can directly influence the development of T-cell immune responses via the release of cytokines and the expression of costimulatory molecules.

3.2.3 NKT Cells

NKT cells are a subset of T cells that express a heavily biased T-cell receptor repertoire as well as the NK-cell receptor CD161; they are deficient in immunological memory. In contrast to conventional T cells, NKT cells recognize glycolipid antigens presented by the nonpolymorphic MHC class I–like molecule CD1d. Although they are not strictly necessary for the generation of a polarized Th cell response, they can modulate the latter by secreting large amounts of IL-4, IL-10, IL-13, as well as IFN-γ or TNF upon T-cell receptor engagement.

A glycosphingolipid originally isolated from the sea sponge Agelas mauritianus, α-galactosylceramide (α-GalCer), is a potent inducer of NKT activity. Optimal stimulation of NKT cells requires direct contact between NKT cells and DC through CD40–CD40–ligand interactions and IL-12 production by DC. Most studies indicate that α-GalCer enhances Th2 polarization, but Th1 differentiation may also be affected.

In vivo activation of NKT cells with α-GalCer ameliorates the diseases caused by *Cryptococcus neoformans* or encephalomyocarditis virus and inhibits the development of the intrahepatocytic stages of *Plasmodium yoelii* and *Plasmodium berghei* in mice. α-GalCer potentiates protective immune responses induced by malaria vaccines.

3.3 Innate Effector Functions

In the first phase of inflammatory responses, chemotactic substances are produced that recruit granulocytes to the site of infection. Microorganisms covered with antibodies or activated complement factors are bound to granulocytes through specific receptors on the plasma membrane, inducing ingestion of the particle (phagocytosis). In addition, tissue macrophages, or monocytes differentiating into activated macrophages, are also capable of phagocytosing microbes via a range of specialized receptors.

The purpose of phagocytosis is to confine microbes in specialized compartments (phagosomes) where they can be exposed to a low pH and to very high

local concentrations of antimicrobial substances, stored in other organelles (such as lysosomes). The acid milieu in the phagolysosome is created by an ATPase-dependent proton pump. Antimicrobial activity can be mediated by effectors ranging from inorganic molecules to polypeptides, carbohydrates, and lipids. Granulocytes and macrophages dispose of a wide range of toxic mechanisms to fight invading microorganisms.

Upon recognition of their cognate ligands, TLRs induce the expression of a variety of host defense genes encoding for antimicrobial peptides and proteins, and for enzyme systems generating toxic oxygen and nitrogen intermediates.

3.3.1 Antimicrobial Peptides and Proteins

Antimicrobial peptides form a large and diverse family of structurally related molecules that have the ability to adopt a shape in which the hydrophobic amino acids are organized on one side of the molecule and the cationic hydrophilic amino acids on the other. For example, defensins are 2 to 6 kDa, cationic, microbicidal peptides that are classified on the basis of their size and pattern of disulfide bonding, into α, β, and θ (extent only in primates) categories. α-defensins are particularly abundant in neutrophils, whereas β-defensins are more often produced by epithelial cells lining, for instance, the skin, the lung, and the genitourinary tract. Defensins are produced constitutively or in response to microbial products. Defensins can kill or inactivate a wide spectrum of bacteria, fungi, or viruses by disrupting the microbial membrane.

Antimicrobial proteins are widely distributed in host defense cells and secretions. Within cells, they are stored in granules (e.g. lysozyme, lactoferrin, RNAse, granulysin, phospholipase A2). When the cells are appropriately stimulated, the granules fuse to internalized cell membranes enclosing ingested microbes, or to the external plasma membrane facing the pericellular space, a process called *degranulation*.

Some antimicrobial proteins are enzymes that lyse their target microbial structure. For example, lysozyme degrades peptidoglycan; similarly, phospholipase A2 destroys bacterial phospholipid membranes. Others disrupt microbial cell walls and membranes or inhibit microbial growth by nonenzymatic mechanisms. For example, lactoferrin chelates iron, thereby depriving microbes of an essential component for growth, and BPI (bacterial permeability increasing protein) binds to LPS of Gram-negative bacteria, first permeabilizing their outer membrane and subsequently destroying their inner membrane. Granulysin is a small protein expressed in the granules of NK cells and cytolytic T lymphocytes that also permeabilizes target membranes.

3.3.2 Reactive Oxygen and Reactive Nitrogen Metabolites (ROI, RNI)

The two most important oxygen-dependent pathways for generating antimicrobial effector molecules are via the phagocyte NADPH oxidase complex and the inducible nitric oxide synthase (iNOS). The former is typically expressed in neutrophilic granulocytes, the latter is most abundant in activated macrophages.

The oxidative burst of granulocytes and macrophages can be triggered by phagocytosis of pathogens, by certain chemoattractants, and by TLR-ligating structural motifs. Reactive oxygen metabolites, such as HOCl, cause the oxidation of thiol groups, heme prosthetic groups, and the chlorination of tyrosine residues, and the

hydroxal radicals incur DNA strand breaks and lipid peroxidation.

Prototypic inducers of iNOS are proinflammatory cytokines, in particular, interferon-gamma, and microbial products. The direct antimicrobial activity of nitric oxide likely involves mutation of DNA, inhibition of DNA repair and synthesis, S-nitrosylation, and peroxidation of membrane lipids. However, RNIs also have multiple immunomodulatory functions that may result in indirect antimicrobial effects.

4 Translating Innate Immune Activation into Regulatory Circuits: Molecular Pathways Shaping Adaptive Immunity

While innate immune cells can often keep invading microorganisms at bay for some time, pathogens have evolved mechanisms to subvert these strategies. TLR ligation on cells of the innate immune system, however, also triggers the expression of genes that will alert T and B cells whose action will then complement and augment the functions of innate defenses. Bridging the gap between innate and adaptive immunity is accomplished by inflammatory cytokines and chemokines that serve as costimulatory molecules to prime T- and B-cell differentiation.

4.1 TLR-initiated Signaling Cascades

After ligation of TLRs, receptor dimerization occurs, triggering recruitment of the adapter MyD88 to the receptor complex. Association of the TIR (Toll/IL-1R) domain of MyD88 with the TIR part of TLRs facilitates association of the death domain of MyD88 with the IL-1R-associated kinase (IRAK). IRAK then autophosphorylates, dissociates from the receptor complex, and interacts with TNF-receptor-associated factor (TRAF) 6. TRAF6 leads to activation of MAP kinases, and by recruiting ECSIT (evolutionarily conserved signaling intermediate in Toll pathways), activates the IKK complex (inhibitor of nuclear factor-κB-kinase complex), thereby releasing NF-κB from its inhibitor so that it can translocate to the nucleus and direct the transcription of inflammatory cytokines. This pathway is used by TLR1, TLR2, TLR4, TLR5, TLR6, TLR7, and TLR9. TIRAP (TIR-domain-containing adaptor protein) is also involved in the MyD88-dependent signaling pathway through TLR2 and TLR4. By contrast, TLR3- and TLR4-mediated activation of interferon-regulatory factor 3 (IRF) and the induction of IFN-β are observed in an MyD88-independent manner. A third TIR-domain-containing adaptor, TRIF, is essential for the MyD88-independent pathway that involves nontypical IKKs. Finally, a fourth adaptor, TRAM (TRIF-related adaptor molecule) is specific to the TLR4-mediated, MyD88-independent/TRIF-dependent pathway.

Further regulatory mechanisms and signaling pathways downstream of TLRs exist, such as the Rac1-PI3K-AKT pathway activated by TLR2. Much remains to be learnt concerning the bifurcation of intracellular pathways that differentially determine type 1 versus type 2 cytokine secretion during infection. In a mycobacterial infection model, TNF production was predominantly ERK-dependent, but independent of p38 MAP kinase activation, whereas IL-10 secretion was predominantly p-38-dependent, but independent of ERK signaling. The use of small molecules as inhibitors of these putatively divergent pathways is an attractive novel

option to selectively skew adaptive immune responses.

At present, there is little evidence that specific TLRs differentially induce Th1 versus Th2 responses. However, certain subsets of DCs respond differently to different PAMPs because they express different TLRs. Thus, plasmacytoid DCs express TLR7 and TLR9, whereas myeloid DCs express many of the remaining TLRs, in particular, TLR3, but not TLR7, and TLR9. This may provide a means of fine-tuning the adaptive response by targeting only certain specialized DCs.

TLR2-dependent activation of mast cells was reported to preferentially induce TNF, IL-4, IL-5, IL-6, and IL-13, whereas TLR4 ligation led to TNF, IL-1β, IL-6, and IL-13, but not IL-4 or IL-5 secretion. In the same study, TLR2-mediated mast cell activation led to degranulation, while TLR4-mediated activation did not.

All MyD88-dependent signals favor Th1 responses. In the absence of MyD88, no Th1 differentiation occurs, whereas Th2 development is seemingly unaffected by MyD88 deficiency. It is unclear whether Th2 differentiation is determined by specific, as yet unknown intracellular signals, or whether it is simply the default pathway. Surprisingly, human patients with a complete recessive IRAK-4 deficiency only seemed to suffer from pyogenic bacterial infections, but were apparently resistant against other ubiquitous microorganisms, such as *Mycobacterium avium*, the latter being clinically highly relevant in patients with hereditary defects in the IL-12/IFN-γ signaling pathways. The fact that significant protective immunity against common pathogens is afforded even in the absence of critical receptors and/or major signaling pathways indicates that there is substantial plasticity and room for compensatory mechanisms in immune cell activation.

There is now also evidence that stimulation via NOD2 can regulate the response to TLR ligation. Nuclear localization of all NF-κB subunits, and, in particular, cREL, was increased in cells deficient for NOD2 following stimulation with muramyl dipeptide, and total splenocytes of NOD2-deficient mice showed greatly increased levels of IL-12, IL-18, and IFN-γ subsequent to TLR2-ligation. Since patients with Crohn's disease (a chronic inflammatory bowel syndrome) have a mutation in NOD2, the lack of repression afforded by the mutant protein likely accounts for the excessive type 1 inflammatory responses present in these patients.

4.2 Molecules Involved in Recruiting Effector Cells

Correct and efficient priming of adaptive responses and, indeed, the overall type of immunity itself heavily depend on the rapid recruitment of professional antigen-presenting cells together with T and B lymphocytes. Thus, molecules coordinating cellular movement from the blood stream into either inflammatory sites, or sites of antigen presentation such as lymph nodes, play a critical role in directing the priming process (Fig. 2). Conversely, differential regulation of surface receptors capable of detecting gradients of chemoattractants is a crucial factor determining the cellular environment in which priming of immune responses takes place.

4.2.1 Defensins

Defensins are not only direct effector molecules of innate antimicrobial immunity but they can also enhance phagocytosis, induce the activation and degranulation of mast cells, and stimulate bronchial epithelial cells to augment

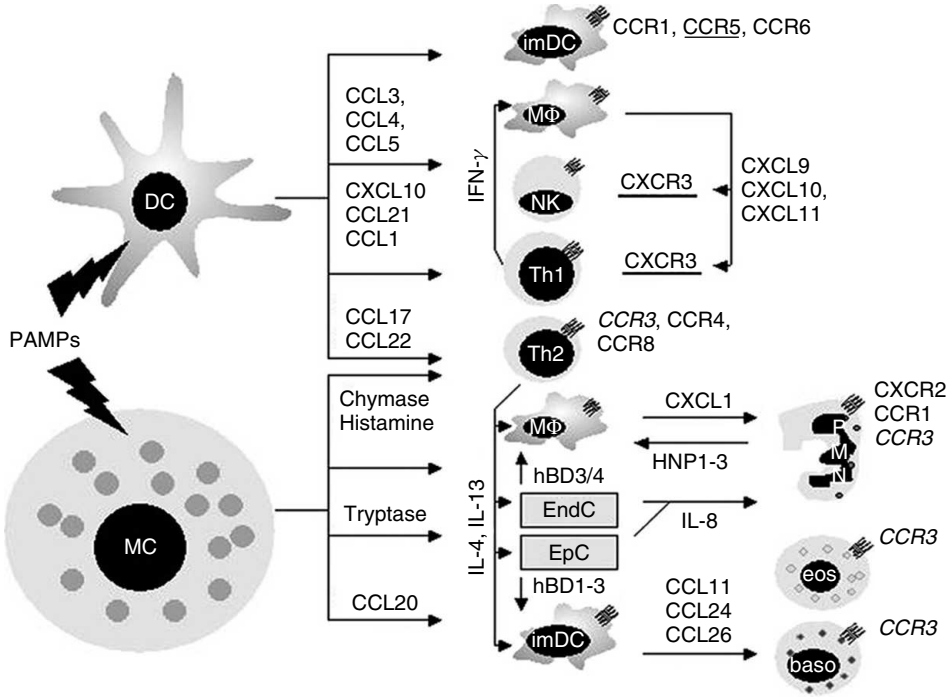

Fig. 2 Major chemokine pathways linking innate and adaptive immune responses. Cells of the innate immune system, triggered by structures on microbes, release chemokines, thereby recruiting different type of cells during the initial phase of the immune response. Type 1 responses are dominated by cells bearing CCR5 and CXCR3 (underlined) and are further amplified by IFN-γ derived from NK and Th1 cells upregulating expression of CXCR3-binding chemokines. Type 2 responses are dominated by cells bearing CCR3 (italics) and are further modulated by IL-4 and IL-13 derived from Th2 cells and mast cells. DC (dendritic cell), MC (mast cell), imDC (immature dendritic cell), MΦ (macrophage), NK (natural killer cell), PMN (polymorphonuclear granulocyte), eos (eosinophil granulocyte), baso (basophil granulocyte), EndC (endothelial cell), EpC (epithelial cell), PAMP (pathogen-associated molecular patterns).

IL-8 production. In this way, defensins are involved in recruiting and activating neutrophils into inflammatory sites. Because some defensins can enhance TNF and IL-1 production – while reducing IL-10 secretion – in monocytes, they may play a role in amplifying the local inflammatory response.

Human neutrophil-derived α-defensins (HNP) 1 and HNP2 are chemotactic for human monocytes and T cells. They are selectively chemotactic for resting CD4/CD45RA and CD8 T cells, whereas human β-defensin (hBD) 2 is chemotactic for immature DCs and CD45RO memory T cells by interacting with human CCR6. HBD 3 and hBD4 are also chemotactic for monocytes via an as yet unidentified receptor. Defensins may also be involved in the maturation of immature DCs either directly or indirectly by inducing the production of TNF and IL-1.

Defensins therefore appear to be important potentiators of T-cell priming.

Indeed, a mixture of HNP1-3, when simultaneously administered with ovalbumin intranasally into C57BL/6 mice, enhanced the production of OVA-specific serum IgG antibody and the generation of IFNγ, IL-5, IL-6, and IL-10 secreting OVA-specific CD4+ T cells. Intraperitoneal injection of HNP1-3 together with keyhole limpet hemocyanin or B-cell lymphoma idiotype Ag into mice not only augmented the levels of Ag-specific IgG but also enhanced the resistance of immunized mice to tumor challenge.

4.2.2 Chemokines

Chemokines are a superfamily of small, heparin-binding cytokines that induce directed migration of various types of leukocytes through interaction with a group of seven-transmembrane G-protein-coupled receptors. TLR activation induces the release of chemokines from tissue macrophages and resident DCs. For example, both TLR2 and TLR4 ligation result in the expression of CCL3, CCL4, and CCL5. TLR2 signaling, however, preferentially leads to secretion of IL-8, while TLR4 signaling leads to CXCL10 production. IL-8 recruits neutrophils to the site of chemokine production, whereas CXCL10 will guide activated T cells into infected tissues. Thus, the discrimination of the pathogen by TLRs and the subsequent production of a distinct subset of chemokines is one of the earliest points at which the immune system tailors its response to specific pathogens.

CCL3 and CCL4 are also crucial for the initial influx of CCR5+ NK cells into infected tissues, as demonstrated in murine models of cytomegalovirus and *Toxoplasma gondii* infection. These NK cells represent an important early source of IFN-γ, providing an environment favorable for Th1 differentiation. IFN-γ in turn induces the expression of the chemokines CXCL9, CXCL10, and CXCL11, instigating the recruitment of activated CXCR3+ T cells and NK cells into the tissue and amplifying the protective response. CXCL10 may also be induced in the absence of IFN-γ following TLR ligation and is also important for the initial influx of CXCR3+ NK cells and T cells.

In terms of modulating humoral immunity, CCL3 treatment stimulated strong antigen-specific serum IgG and IGM responses, while CCL4 administration promoted higher serum IgA and IgE responses, as well as higher titers of antigen-specific mucosal secretory IgA levels in mice. These chemokines may therefore differentially enhance serum and mucosal humoral immune responses.

Immature DCs express several chemokine receptors, including CCR1, CCR5, and CCR6. These are important for recruiting imDCs in response to early pathogen-induced release of CCL3, CCL4, and CCL20, and for keeping them in the tissue. After TLR-mediated activation, however, DCs downmodulate the expression of these chemokine receptors and upregulate the expression of CCR7, allowing them to respond to CCL19 and CCL21 expressed in lymphatic tissues. This serves as a stimulus for DCs to leave the tissue and ultimately migrate into the T-cell rich regions of lymph nodes where priming of T cells occurs. Generally speaking, Th1-dominated responses are associated with the recruitment of CCR5- or CXCR3-bearing cells, whereas Th2-dominated responses are more closely dependent on the influx of CCR3-expressing cells.

Mast cell granule–derived serine proteases also play a major role in recruiting cells to the site of infection. Chymase, a serine protease found in human mast cells,

induces monocyte and neutrophil migration directly. Murine mast cell protease-6, also known as *tryptase*, induces neutrophil extravasation indirectly by enhancing endothelial cell IL-8 production. In addition, histamine is a major mediator synthesized by mast cells. Vasodilation and inflammation are among the prime consequences of its being released from the granules in which it is stored. Histamine promotes the expression of Th2 polarizing (e.g. IL-6 and IL-10) cytokines from human lung macrophages. Histamine also inhibits IL-12 production and augments IL-10 secretion of maturing monocyte-derived DC, resulting in a change from Th1 to Th2 in their T-cell polarizing function. In addition, activated human plasmacytoid DCs respond to histamine by a marked downregulation of IFN-α and TNF.

Most importantly, mast cell granules contain preformed TNF, which is a major mediator of neutrophil influx into sites of mast cell activation. Upon appropriate stimulation, mast cells are also capable of releasing – without degranulation – CCL20, a potent chemoattractant for imDC and T cells.

4.3 Molecules Involved in T- and B-Cell Differentiation

Cytokines provide the most direct link between innate and adaptive immunity because they regulate the communication between dendritic cells, lymphocytes, and other host cells in the course of an immune response. The local milieu of cytokines determines the commitment of T cells to a Th1/Tc1 or Th2/Tc2 type, as well as the immunoglobulin class switch in B cells, and drives the overall immune response toward either tolerance or immunity (Fig. 3).

4.3.1 Th1-inducing Cytokines

Type I Interferons (*IFNs*) were among the first cytokines identified, originally because of their antiviral activity and their effects on the cells of the innate response. IFNs have recently been shown to play an important role in connecting innate and adaptive immunity by acting on T cells and dendritic cells. The term IFN-α/β defines a large group of closely related cytokines, which exert their activity by binding to a common receptor, the IFN-α/β receptor. These cytokines include IFN-α, -β, -δ, -τ, -ω, and -κ.

Although virtually any cell type can express IFN-α/β following viral infection, NIPCs produce 200 to 1000 times more IFN than other blood cells after microbial infection or following stimulation with bacterial components such as LPS and bacterial DNA. IFN-α/β produced by NIPCs and macrophages can enhance the efficiency of the innate immune response by activating natural killer and other host reactive cells.

Type I IFNs provide important signals for the differentiation and activation of DCs. In particular, IFN-α/β promotes the rapid differentiation of GM-CSF-treated human monocytes into DCs with enhanced T-cell stimulatory capacity. Importantly, IFN-α/β plus GM-CSF-matured DCs induced a potent primary antibody response when pulsed with antigen and injected into SCID mice reconstituted with autologous peripheral blood lymphocytes.

In addition, IFN-α/β treatment of imDCs induces phenotypical and functional maturation of these cells, as shown by their expression of DC markers and their migratory response to chemokines. The effects of IFN-α/β on DC maturation imply that they can exert an adjuvant activity. Indeed, experiments in mice revealed that (1) type I IFNs are extremely potent

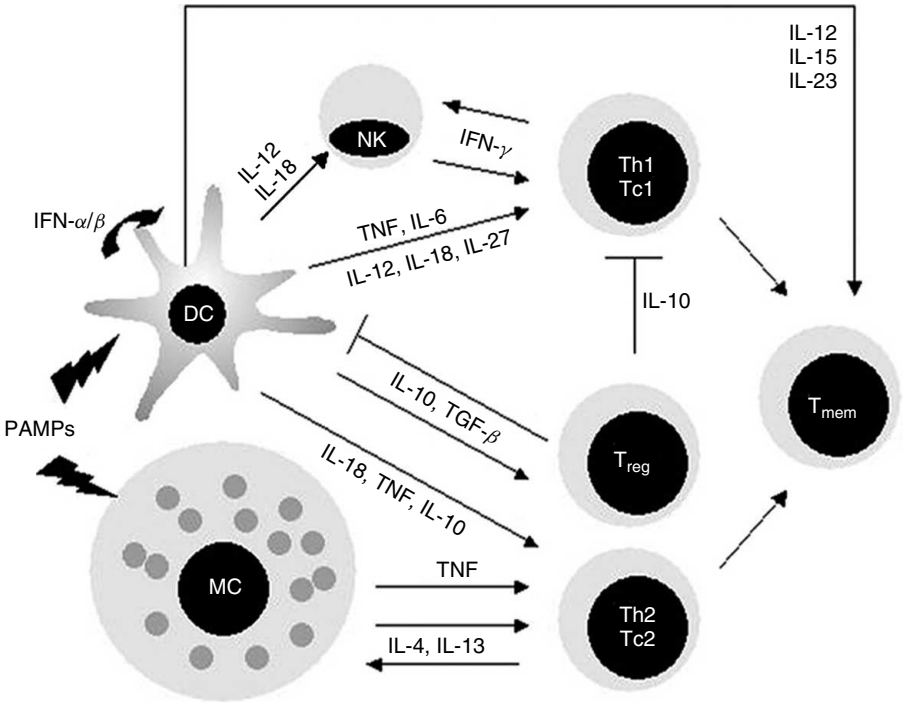

Fig. 3 Major cytokine pathways linking innate and adaptive immune responses. Cells of the immune system, triggered by structures on microbes, release cytokines that skew T-cell development into a T helper 1/T cytolytic 1 (Th1/Tc1) or a Th2/Tc2 pathway. Feedback loops involving IFN-γ (type 1 immunity) or IL-10, TGF-β, IL-4, and IL-13 (type 2 immunity) are indicated. DC (dendritic cell), MC (mast cell), T_{reg} (regulatory, CD4+CD25+ T cell), T_{mem} (memory T cell).

adjuvants when injected into immuncompetent mice with a reference antigen; (2) IFNs directly act on DCs; and (3) the natural adjuvant activity associated with infectious agents is mediated by IFN-α/β.

Interferon-gamma (*IFN-*γ) is a potent activator of the antimicrobial functions of phagocytes, and plays an important role in resistance to many pathogenic bacteria, fungi, and intracellular parasites. It is mainly produced by Th1 cells and natural killer cells, but other T-cell subsets such as NKT cells, CD8+ T cells, and $\gamma\delta$ T cells are also capable of secreting IFN-γ. Furthermore, macrophages, dendritic cells, and B cells are able to produce IFN-γ when appropriately stimulated. Both type I and type II interferons activate natural killer (NK) cells to kill virus-infected cells and release cytokines.

Interleukin-18 (*IL-18*) is a proinflammatory cytokine that belongs to the IL-1 cytokine family, owing to its structure, receptor family, and signal transduction pathways. Similar to IL-1β, IL-18 is synthesized as a precursor requiring caspase-1 for cleavage into an active IL-18 molecule. Produced mainly by antigen-presenting cells, it induces the production of Th1 cytokines, for example, IFN-γ, and enhances cell-mediated cytotoxicity in the presence of IL-12. Interestingly, IL-18, in the absence

of IL-12, induces the production of Th2-related cytokines from T and NK cells and basophils/mast cells. Therefore, IL-18 should be seen as a cytokine that enhances innate immunity and both Th1- and Th2-driven immune responses.

Interleukin-15 (*IL-15*) and IL-2 both utilize the IL-2Rβ and the IL-2Rγ chain as receptor structures; therefore, the two cytokines induce similar biological activities, such as stimulating NK, T, and B cells to proliferate, secrete cytokines, become cytotoxic, or produce antibodies. Nevertheless, there are major differences between these two cytokines in terms of their cellular origins and the mechanisms controlling their synthesis and secretion. In contrast to the predominantly T-cell-restricted expression of IL-2 transcripts, there is widespread constitutive expression of IL-15 mRNA in a variety of tissues including placenta, skeletal muscle, kidney, lung, heart, fibroblasts, epithelial cells, and activated monocytes. However, IL-15 protein was found to be produced only by a limited number of cells such as activated macrophages and epithelial cells.

Findings obtained from gene-targeted mice deficient in individual components of the IL-2/IL-15 system demonstrate distinct roles of IL-15 and IL-2 for the activation of the innate immune system. IL-15 is of pivotal importance for maintaining NK-cell homeostasis, for promoting the differentiation of $\gamma\delta$T cells, and for inducing CD8+ memory T cells. IL-15 also promotes monocyte differentiation into Langerhans' cells. Furthermore, some of the effects induced by IFN-α on the differentiation and/or activation of DCs seem to be mediated by IL-15, which is produced by DCs in response to IFN-α. In addition, IL-15 is a potent inhibitor of apoptosis. Phagocytosis and chemokine production of neutrophils are strongly enhanced by IL-15, and expression of IL-15 in macrophages is upregulated in response to numerous signals that trigger innate immune responses, such as LPS, mycobacteria, or *T. gondii*. Most importantly, exogenous IL-15 has been shown to improve host defense against and/or clearance of Salmonella, *P. falciparum*, and *C. neoformans*.

Interleukin-12 (*IL-12*) is a heterodimeric proinflammatory cytokine formed by a 35-kDa light chain (p35) and a 40-kDa heavy chain (p40), which is produced mainly by DCs and phagocytes (monocytes/macrophages and neutrophils) in response to pathogens during infection. In synergy with TNF and IL-18, IL-12 can induce the production of large amounts of IFN-γ by NK cells, a crucial event in the early phase of the innate immune response.

IL-12 acts not only on NK cells but also on NKT cells and T cells, inducing proliferation, cytotoxic activity, and the differentiation of Th1 cells. T cell and NK cells, in turn, enhance the production of IL-12 through IFN-γ, giving origin to a positive feedback during Th1 immune responses. Surprisingly, both IL-4 and IL-13 are also potent IL-12 inducers. Recent data argue against an absolute requirement for IL-12 for Th1 responses, since two new members of the family of IL-12p40-related heterodimeric cytokines, IL-23 and IL-27, are also involved in the maturation of Th1 responses.

Interleukin-23 (*IL-23*) is a heterodimer, comprising IL-12p40 and the recently cloned IL-23-specific p19 subunit, and binds to a receptor complex composed of the IL-12Rβ1 subunit and a private IL-23R. IL-12 and IL-23 both promote cellular immunity by inducing IFN-γ production and proliferative responses in target cells.

IL-23, which is produced predominantly by macrophages and dendritic cells, does differ from IL-12 in the T-cell subsets that it targets. Whereas IL-12 acts on naïve and effector CD4+ T cells, IL-23 preferentially acts on memory CD4+ T cells. Recent studies of IL-23 receptor expression and IL-23 overexpression in transgenic mice revealed that IL-23 plays a crucial role in autoimmune inflammation in the brain by a direct action on macrophage function.

Interleukin-27 (IL-27) is a new heterodimeric cytokine that consists of an IL-12p40-related protein, EBI-3 (Epstein–Barr virus-induced gene 3), and p28, an IL-12p35-related polypeptide. IL-27 is a strong inducer of IFN-γ production, particularly in synergy with IL-12 and IL-18. Mice deficient for EBI-3 have markedly decreased numbers of invariant NKT cells, which, in addition, produce significantly less IL-4 and IFN-γ compared to normal mice. Thus, EBI-3 also plays a critical regulatory role in the induction of Th2-type immune responses.

IL-27 is produced by activated antigen-presenting cells and is mostly involved in the Th1 commitment of naive CD4+ T cells, mediated by IL-27R-dependent upregulation of the major signal-transducing IL-12Rβ2 chain. In contrast, IL-23 (like IL-15) is critically important for the maintenance of immunological memory, since IL-23R is expressed on memory, but not on naïve T cells.

IL-27 is also involved in modulating inflammatory processes, since mice deficient in a component of the IL-27 receptor (WSX-1) suffer from a vastly enhanced tissue-destroying inflammatory response during infections with *T. cruzi* and *M. tuberculosis*.

Interleukin-6 (IL-6) is a potent differentiation factor for B and T cells. IL-6 produced upon TLR ligation in DCs is a necessary requirement for T-cell activation whenever CD4+CD25 regulatory T cells are present. Indeed, IL-6-deficient mice were severely compromised in their induction of OVA-specific immune responses as long as CD4+CD25+ cells were present, but not when the latter were removed. Therefore, innate immune recognition by TLRs seems to control the activation of adaptive immune responses by at least two distinct mechanisms: the induction of costimulatory molecules on DCs and the production of IL-6, which renders pathogen-specific T cells refractory to the suppressive activity of CD4+CD25+ regulatory T cells. Since release of suppression is necessary for efficient T-cell priming during vaccination, IL-6 is an attractive candidate for an immunopotentiating adjuvant. Indeed, when recombinant human IL-6 was used as an adjuvant in a subunit vaccine against tuberculosis consisting of the culture filtrate proteins of *M. tuberculosis* emulsified in the adjuvant dimethyl-dioctadecylammonium bromide, an increased Th1 response characterized by enhanced IFN-γ production and cell proliferation was observed. Moreover, a specific local IgA response to heterologous antigen was increased in the lungs of mice when genes for murine IL-6 were coexpressed in recombinant vaccinia virus and inoculated intranasally.

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is by far the most widely used hematopoietic growth factor to augment immune responses. It was initially defined as survival and growth factor for hematopoietic progenitor cells, and as a differentiation and activating factor for granulocytic and monocytic cells. GM-CSF plays a crucial role *in vitro* for the differentiation of dendritic cells from precursor cells from bone marrow and peripheral blood.

GM-CSF is secreted by several different cell types, including fibroblasts, endothelial cells, and smooth muscle cells, following stimulation by proinflammatory cytokines such as IL-1 and TNF-α. LPS stimulates GM-CSF secretion from monocytes or macrophages, which could further potentiate the cellular response to LPS. It is known since the early seventies that endotoxin administration in mice raises the serum levels of GM-CSF. The injection of GM-CSF in mice leads to an increase in the numbers of neutrophils and cycling peritoneal macrophages. It was therefore proposed that GM-CSF blockade may have some anti-inflammatory effects and be employed for host protection.

The immunomodulatory effects, which include the activation and augmentation of many of the functions of neutrophils, monocytes, macrophages, and dendritic cells, make this cytokine a candidate for a natural vaccine adjuvant. Indeed, the use of soluble GM-CSF (fusion-protein), as well as gene-transduced, plasmid DNA, in vaccination-based therapies has proven to be relevant for the induction of cellular as well as humoral immune responses, therefore enhancing host defenses against a broad spectrum of invading organisms.

4.3.2 Th2-inducing Cytokines

Interleukin-4 (IL-4) is one of a number of cytokines produced by activated mast cells, and plays a predominant role in many immune and inflammatory reactions. Two biological activities have been defined in detail: IL-4 induces selective IgG1 and IgE isotype switching in B cells and promotes the differentiation of naïve CD4 T cells into a subset of T helper cells that express IL-4 as well as IL-5, IL-10, and IL-13. These cytokines and Ig isotypes are hallmarks of a Th2 response and play a protective role in immunity to extracellular pathogens.

Interleukin-13 (IL-13) belongs to the Th2 cytokine family and is structurally related to IL-4, belonging to the same α-helix protein family. The production of IL-4 and IL-13 is restricted to activated T lymphocytes (in particular, Th2 cells), mast cells, basophils, natural killer cells, and dendritic cells. Both cytokines are functionally active on a wide variety of cell types such as macrophages, NK cells, eosinophils, and mast cells. IL-4 and IL-13 act synergistically to promote DC maturation induced by bacterial products or proinflammatory mediators (such as TNF or CD40 ligand), as evaluated by upregulation of MHC class II and costimulatory molecules. Both cytokines show important immunosuppressive and anti-inflammatory activities, which include the inhibition of proinflammatory cytokines (like IL-1, IL-6, IL-10, IL-12, and TNF-α) and chemokines (like IL-8, CCL3-5, and CCL11).

In mice, a coordinate regulatory sequence element, situated in the intergenic region between the genes for IL-4 and IL-13, was found to be critical for the optimal expression of type 2 cytokines. Mice deficient in this regulator had normal, IL-4-producing mast cells, while their capacity to develop Th2 cells was completely absent *in vitro* and *in vivo*.

Initially, IL-13 was thought to be functionally redundant with IL-4 as a predominant anti-inflammatory factor secreted during type-2 T-cell responses. However, IL-13 possesses a number of additional properties that distinguish it from IL-4: for example, IL-13 plays a key protective role in the expulsion of helminths from the gut and, unlike IL-4, is the major contributor to granulomatous pathology in schistosomiasis.

Therapeutic administration of IL-13 inhibitors in mice successfully prevents allergic responses and Schistosoma

egg–induced lung pathology. Agonist IL-13-treatment in mice, by inducing mastocytosis, eosinophilia, IgE synthesis, and mucus production, protects against ectoparasites and gastrointestinal worms and suppresses inflammation induced by Th1 cytokines. Future studies are required to understand if this scenario holds true in humans.

Interleukin-10 (IL-10) was initially described as a mouse Th2 cell product, but is now known to be produced by a wide range of cell types, including T cells, B cells, keratinocytes, monocytes/macrophages, and dendritic cells. It activates B lymphocytes and NK cells and has an inhibitory function on T cell and macrophage activation. IL-10 not only reduces the production of proinflammatory cytokines such as TNF-α, IL-1, IL-6, IL-12, IFN-γ, and GM-CSF but also of chemokines like IL-8 and CCL3. Furthermore, IL-10 downregulates the production of molecules important in triggering specific immunity such as MHC class II and costimulatory molecules, CD86, therefore inhibiting antigen-presenting cell maturation.

Some bacterial pathogens, like mycobacteria, *Bordetella pertussis*, or *Yersinia enterocolitica*, have developed mechanisms for modulating cytokine production by host cells. These bacteria can induce the production of anti-inflammatory cytokines, such as IL-10 and TGF-β, which dampen the immune response. These immunosuppressive cytokines may also contribute to the generation of so-called regulatory T cells, which downregulate immune activation.

It is noteworthy that IL-10 also is a potent stimulator of NK cell activity. Cytotoxic lysis of infected cells may contribute to the clearance of pathogens and facilitate antigen acquisition from dead cells for cross-priming by activated dendritic cells, providing a link between the innate and the adaptive immune responses.

The transforming growth factor (*TGF*)-β, family comprises three closely related cytokines with potent immunoregulatory proteins that influence both positively and negatively the process of inflammation and repair. TGF-β regulates processes such as angiogenesis, chemotaxis, fibroblast proliferation, and the controlled synthesis and degradation of matrix proteins, for example, collagen and fibronectin.

Many cell types express TGF-β constitutively and produce more when stimulated. These include macrophages, T and B cells, platelets, and fibroblasts. Importantly, TGF-β is also produced by regulatory T cells, which downmodulate the function of Th1 and other immune cells. TGF-β inhibits immune functions of T and B cells by reducing TNF-α and IL-1 production in peripheral blood monocytes, and directly inhibits DC maturation. In a model of murine malaria, low amounts of active TGF-β production by splenic mononuclear cells were associated with a lethal outcome, and anti-TGF-β treatment transformed a normal resolving infection into a lethal one characterized by a hyperproduction of proinflammatory cytokines.

5 Practical Implications

Because TLRs play a central role in directing both innate and adaptive immune responses, reagents ligating TLRs or interfering with TLR ligation are currently the subject of intense investigation in both preventive and therapeutic medicine.

Inactivated pathogens and highly purified recombinant proteins or peptides without adjuvants do not elicit efficient

Th cell responses. Therefore, it is imperative to optimize strategies that will enhance antigen presentation by inducing a favorable costimulatory milieu. Biological adjuvants do this by activating TLRs, and thereby, stimulating innate immune responses.

Live carrier vaccines, in particular, have the advantage of bringing a variety of strongly activating PAMPs with them. For example, the widely used tuberculosis vaccine strain, *Mycobacterium bovis* BCG, is a powerful inducer of T-cell responses because it contains PG, LAM, lipoproteins, lipopeptides, and CpG motifs as TLR agonists, and because it can persist for some time within antigen-presenting cells, providing long-lasting T-cell priming. However, the particular combination of PAMPs in a given bacterial strain may also favor some undesired responses because of a significant cross-regulation of PAMPs interacting with different pattern-recognition receptors simultaneously. For instance, ligation of the mannose receptor (with ManLAM, present on certain mycobacterial strains) at the same time as stimulation of TLRs (e.g. TLR4 with LPS) reduces the production of IL-12 in DCs compared to DCs stimulated with the TLR agonist only. This may effectively diminish the adjuvant Th1 inducing potency of, for example, a BCG carrier vaccine. Similar mechanisms may be operative in other bacterial carrier systems, although the precise ligands and receptors involved are probably quite different. As a consequence, the combination of highly purified, recombinant molecules (PAMPs, chemokines, and cytokines) may prove to be superior to bacterial vaccine strains, because their individual dose and composition can be modified to fit the particular requirements of the vaccinee.

Conversely, interfering with TLR ligation and/or signaling may prove to be a worthwhile anti-inflammatory strategy. For example, septic shock continues to be fraught with a very high mortality rate, and attempts to modulate mediator cytokine secretion or function (for example, with anti-TNF antibodies) have not been successful. It appears straightforward and attractive to blunt the overzealous inflammatory response by inhibiting sensory input, for example, by blocking TLR ligation using synthetic compounds that bind to TLRs without activating them. Although far from eliminating the actual cause for the inflammatory response, this would interfere with a very proximal event in the signaling cascade leading to organ failure. Also, depending on whether signal transducers such as MyD88 or TRIF can be effectively blocked, this would provide a broader approach than neutralizing endotoxin (TLR4-ligand) or lipoteichoic acid (TLR2-ligand) only.

Keywords

Agnosia
It is the inability to recognize and identify objects or persons despite having knowledge of the characteristics of those objects or persons.

Amaurosis
It is a partial or complete loss of sight.

Apraxia
It is the inability to execute a voluntary motor movement despite being able to demonstrate normal muscle function.

Ataxia
It is an incoordination and lack of balance.

Dyslexia
It is a difficulty (in learning) to read.

Dysphasia
It is a group of speech disorders with an impairment of expression by speech, or an impairment of the comprehension of spoken language. More severe forms of dysphasia are called aphasia.

Excitotoxicity
It is an excessive exposure to glutamate or related compounds killing brain neurons by overstimulating them.

Hemianopia
It is a blindness or reduction in vision in one half of the visual field.

Hemiparesis
It is a weakness on one side of the body.

Ischemic Tolerance
Ischemic tolerance or ischemic preconditioning is an intrinsic adaptive response to a mild ischemic stimulus protecting from an otherwise "lethal" ischemic event.

Penumbra
It is an area of constrained blood flow with partially preserved energy metabolism lying between the lethally damaged core and the normal brain.

SAGE
Serial analysis of gene expression, a technique for profiling gene expression.

The current understanding of stroke pathophysiology is basically founded on experimental models. Among these, *in vitro* models with primary cultures of cerebral cells permit stroke pathophysiology to be examined on a molecular level, while animal models (mainly mouse and rat) are used to evaluate medical intervention. There is a highly complex sequence of events leading to the eventual ischemic cerebral damage that follows a well-defined spatiotemporal pattern. Overwhelming excitotoxicity leads to early necrotic cell death in what is to become the core of the infarction, while the tissue damage in the surrounding zone called *penumbra* happens on a longer timescale. The excitotoxic or inflammatory mechanisms are milder, bearing the biochemical hallmarks of apoptosis. The brain cells, challenged by such a large-scale assault, activate endogenous protective programs. These have been studied by experimentally inducing ischemic tolerance (i.e. ischemic preconditioning). Importantly, cerebral ischemia not only affects the brain but also impacts other systems. For example, stroke induces dramatic immunodepression through overactivation of the sympathetic nervous system. As a result, severe bacterial infections such as pneumonia occur. The complex signaling cascades not only decide over cell survival in the brain and the neurological deficit but also over mortality after stroke from extracerebral complications. Their ability to govern not only the maturation of the eventual infarction but also the immune system make them a promising target for intervention and the development of neuroprotective drugs.

1 Introduction

In the United States, more than 600 000 people per year suffer from strokes, and, among acutely hospitalized neurological patients, stroke patients make up the largest share – about 50%. Currently, there are about 4 million stroke survivors in the United States. Mortality from stroke is an estimated 25%, which makes it the third major cause of death in industrialized countries. Because of the high rate of severe permanent disability, stroke is a burden not only for the affected patients and their families but also for national economies: In the United States, it is estimated that the annual costs caused by strokes ranges between 30 and 40 billion dollars. In the United Kingdom, the cost of

one individual patient amounts to £30 000 over 5 years.

The term stroke accommodates a variety of different conditions. About 85% of all strokes are caused by cerebral ischemia due to vessel occlusion. Primary cerebral bleeding is rare in comparison – 15%. Of the ischemic strokes, 75% are caused by emboli, of either arterial or cardial origin, while microvascular occlusion, that is, hyalinosis or *in situ* thrombosis is responsible for 20% of cases. Hemodynamic ischemia, caused by stenoses of brain-supplying arteries, account for less than 5% of ischemic strokes.

The prospective risk of suffering an ischemic stroke is partially a function of social and behavioral (nutrition, tobacco use, stress) factors and long-standing disorders like hypertension, diabetes, disorders of cholesterol and lipid metabolism, and obesity. Atherosclerosis is not only the main underlying condition in ischemic stroke but also in coronary heart disease and peripheral vascular disease. Moreover, the genetic background of affected individuals is coming under increasing scientific scrutiny, as might be expected for familial stroke conditions like CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucencephalopathy), which is characterized by relapsing subcortical ischemia. The condition is caused by a mutation in the *notch3* gene on chromosome 19. MELAS (mitochondrial encephalopathy, lactate acidosis, stroke-like episodes) is another rare familial stroke disorder, characterized by migraine, grand-mal seizures, and recurrent cortical infarctions. The condition is caused by a range of mutations in the mitochondrial genome, which explains its maternal inheritance. The severity of the phenotype depends mainly on the mutation locus and on the proportion of mutated mitochondrial genomes in the cerebral mosaic. However, family and twin studies suggest that genetic factors are likely to be involved in common types of ischemic stroke, not just in rare and well-defined familial stroke disorders.

A locus on chromosome 5q12 described for the Icelandic population seemed to increase stroke susceptibility significantly. The responsible gene has been identified as phosphodiesterase 4D (pde4d). The risk-conveying polymorphisms are located in the gene-regulatory part. This hints at a defect in the regulation of the encoded cAMP degrading protein. Phosphodiesterase 4D belongs to a group of proteins that are drug targets in the treatment of asthma, erectile dysfunction, and inflammation.

Symptoms of focal cerebral ischemia depend on the individual affected vessel with its typical supply territory. Table 1 summarizes the frequency of affection and the typical clinical syndromes for the main brain arteries. Stroke mortality is rated between 20 and 30%. Unfavorable prognostic factors are old age, initial coma, papillary asymmetry, coronary heart disease, and heart failure. Pyrexia and infections (pneumonia, in particular) deteriorate the prognosis, particularly during the initial phase (see below). Of the surviving patients, one-third improve within a week, 40% remain unchanged in their disability, and 20% deteriorate further during the first week.

A great deal of our knowledge about the pathophysiology of stroke comes from experimental research. The experimental animal models follow two main paradigms. One is the model of focal cerebral ischemia as a model of ischemic stroke. The other is the model of global cerebral ischemia as model of circulatory arrest. For obvious

Tab. 1 Territorial stroke syndromes.

Anterior territory		
Middle cerebral artery (MCA)	(≈60%)	Hemiparesis mainly arm, hemihypaesthesia, hemianopia, dysphasia or neglect
Anterior cerebral artery (ACA)	(4%)	Hemiparesis mainly leg, urinary incontinence, apraxia
Anterior choroidal artery (AchA)	(8%)	Hemiparesis, hemihypaesthesia, hemianopia
Posterior territory		
Vertebral/basilar artery (VA/BA)	(10%)	Vertigo, diplopia, bilateral hypaesthesia, and paresis, crossed syndromes, amaurosis, ataxia, headache, coma
Cerebellum posterior/anterior inferior cerebellar artery (PICA/AICA)	(7%)	Headache, ataxia, vertigo, gaze palsy, facial weakness, deafness
Posterior cerebral artery (PCA)	(9%)	Hemianopia, dyslexia, visual agnosia

reasons, we will focus mainly at studies of focal cerebral ischemia. The bulk of experimental studies has been carried out with rats and mice, although some primates have been used. In rodents, ischemia is mostly induced by intravascular occlusion of the MCA, using a monofilament just exceeding the critical vessel diameter. Depending on the duration of occlusion, we distinguish permanent from transient ischemia models. The latter are also used as models for spontaneous reperfusion or for the state after successful lysis therapy with recombinant tissue plasminogen activator (rtPA) in humans, respectively.

In models of cerebral ischemia, perfusion to the brain is impeded by some form of manipulation. Since the essence of ischemic stroke is vascular occlusion, it is not surprising that in these models the extent of the eventual infarction can be predicted quite accurately from the degree of reduction in regional cerebral blood flow (rCBF). Thus, if the rCBF is reduced to less than 25% of normal, the likelihood of infarction in a given volume of brain tissue is greater than 95%. In contrast, the likelihood of infarction is less than 5% if rCBF does not fall below 50% of normal. These thresholds have been established in comparative human PET and MRI studies and correspond with experimental data from animal models. Thus, the initial reduced rCBF determines the extent of the anticipated infarction. This, however, holds only with the provision that a spontaneous or therapeutic reperfusion does not take place.

We now look at ischemic infarction as the result of a complex and prolonged process of infarct maturation rather than a simple result of reduced regional perfusion. As brain tissue has a high demand for oxygen and glucose, a disruption of perfusion leads to substrate depletion within few minutes, while toxic metabolites accumulate. The ensuing cellular energy deficit leads to a collapse of the established ion gradients and the membrane potential. Neurons and glial cells depolarize. Depending on the extent and the duration of this energy deficiency, the cells will suffer not only a functional but also a structural breakdown. The highly complex sequence of events within the ischemic area follows a fairly well-defined

stereotypic spatiotemporal pattern, which we will discuss below in more detail. The concept of the ischemic *penumbra* is crucial to the understanding of these mechanisms. The cascade of ischemic damage begins with *excitotoxicity*, the formation of reactive *oxygen free radicals*, the increasing *tissue acidosis* and the occurrence of *periinfarct-depolarizations*. It is followed by the stages of *inflammation* and programmed cell death (*apoptosis*). This is associated with *DNA damage* that, in turn, induces *DNA repair programs*. Although the process is not yet fully understood, we know that chromatin remodeling, that is, *epigenetic mechanisms*, and the activation of transcription factors induce complex *gene programs*. These changes initiate the expression of destructive proteins involved in inflammation and apoptosis, as well as a host of protective genes that help repair the ischemic damage. It is the activation of these protective genes that builds up *ischemic tolerance*. Among the many newly discovered protective mechanisms, *endogenous* and *exogenous cell replacements* have met with a lot of interest. Apart from these autochthonous mechanisms of the brain tissue, there are other mechanisms on a systemic scale, which bear important clinical significance. For instance, the phenomenon of *stroke-induced immunodepression* can help understand why stroke patients are at such high risk of contracting serious bacterial infections. Neuroprotective treatment must be based on an understanding of these mechanisms.

2 The Penumbra Concept

In the ischemic brain, we commonly distinguish two tissue volumes – the core of the infarction and the surrounding zone, known as *ischemic penumbra* – the underperfused and metabolically compromised margin surrounding the irrevocably damaged core. Core and penumbra are characterized by two different kinds of cell death: necrosis and apoptosis (which is also called programmed cell death or delayed neuronal cell death). The severe perfusion deficit in the core causes a breakdown of metabolic processes, cellular energy supply, and ion homeostasis, which causes the cells to lose their integrity within minutes. Thus, acute necrosis of cell and tissue prevails in the core. In the penumbra, some residual perfusion is maintained by collateral vessels, which may be unable to maintain the full functional metabolism, but prevents immediate structural disintegration. However, over time, the alteration of cellular homeostasis causes more and more cells to die, and the volume of the infarction increases (Fig. 1). The penumbra has thus to be considered as tissue at risk during the maturation of the infarct. In this region, apoptosis and inflammatory signaling cascades play an important role. It may initially constitute 50% of the volume that will end up as infarction. The mechanisms that lead to delayed cell death within the penumbra are the subject of intense research, as they provide targets for a specific neuroprotective therapy in brain regions challenged by ischemia, but which are still viable.

3 Excitotoxicity

The depolarization of neurons and glia due to local energy deficit causes the activation of voltage-gated calcium channels and the release of excitatory amino

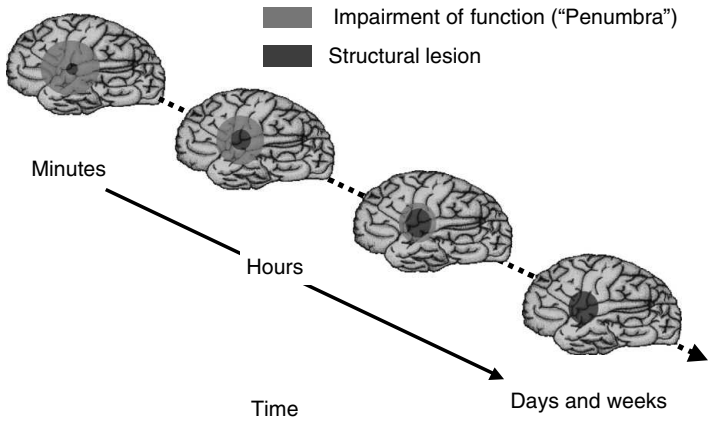

Fig. 1 Regression of the functional neurological deficit while the structural lesion grows. Early in the course of stroke, clinical symptoms mostly reflect an impairment of function (green) but not necessarily a structural lesion (blue). Over time, some areas either spontaneously, or because of therapy, recover function, which explains why symptoms in patients can regress, while the structural lesion actually grows (Reprinted from Dirnagl, U., Iadecola, C., Moskowitz, M.A. (1999) Pathobiology of ischaemic stroke: an integrated view, *Trends Neurosci.* **22**, 391–397, with permission from Elsevier) (See color plate p. xxiii).

acids into the extracellular space. Glutamate, in particular, which, under normal cellular energy conditions, would be immediately taken up presynaptically or through astrocytes, now remains in the extracellular space where it accumulates dramatically. Through the activation of NMDA and AMPA subtype glutamate receptors, the intracellular Ca^{2+} level rises (Fig. 2). Furthermore, metabotropic glutamate receptors are activated through the induction of phospholipase C (PLC) and inositol triphosphate (IP_3), and calcium is mobilized from intracellular stores. Additionally, the AMPA receptor induces an increase of intracellular Na^+ and Cl levels.

Altogether, the result is a massive disturbance of ion homeostasis, accompanied by passive water influx and cell edema. Ultimately, these massive changes in cell volume account for osmotic cell lysis. This lytic type of cell death, also referred to as *necrosis*, is primarily observed in the core of the infarction. Cells that escape this most dramatic form of disintegration, as they can not in the core but in the penumbra, excitotoxicity may be an initiator of molecular events that lead to apoptosis and inflammation.

4 Oxygen Free Radicals

As a consequence of ischemia and particularly of reperfusion, reactive oxygen free radicals such as superoxide, hydrogen peroxide, and hydroxyl radicals are generated. Nitric oxide is generated via the activation of the calcium calmodulin–dependent nitric oxide synthase (NOS); it reacts with superoxide radicals and forms thus the highly reactive peroxynitrite radical.

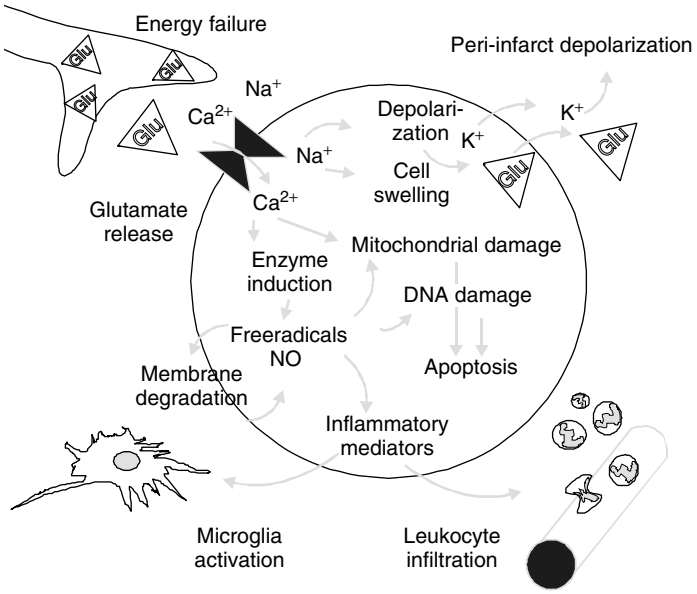

Fig. 2 Simplified overview of pathophysiological mechanisms in the focally ischemic brain. Energy failure leads to the depolarization of neurons. Activation of specific glutamate receptors dramatically increases intracellular Ca^{2+}, Na^{+}, Cl^{-} levels while K^{+} is released into the extracellular space. Diffusion of glutamate (Glu) and K^{+} in the extracellular space can propagate a series of spreading waves of depolarization (peri-infarct depolarizations). Water shifts to the intracellular space via osmotic gradients and cells swell (oedema). The universal intracellular messenger Ca^{2+} overactivates numerous enzyme systems (proteases, lipases, endonucleases, etc.). Free radicals are generated, which damage membranes (lipolysis), mitochondria, and DNA, in turn triggering caspase-mediated cell death (apoptosis). Free radicals also induce the formation of inflammatory mediators, which activate microglia and lead to the invasion of blood-borne inflammatory cells (leukocyte infiltration) via upregulation of endothelial adhesion molecules (Reprinted from Dirnagl, U., Iadecola, C., Moskowitz, M.A. (1999) Pathobiology of ischaemic stroke: an integrated view, *Trends Neurosci.* **22**, 391–397, with permission from Elsevier).

Further sources of oxygen free radicals in the damaged brain tissue are the breakdown products of the adenosine phosphates, which contribute to radical production via xanthine oxidase and the iron-catalyzed Haber–Weiss reaction. The many different radical species that are thus formed can react with virtually any cellular components (carbohydrates, amino acids, DNA, phospholipids) and damage them. The peroxidation of membrane lipids releases further radicals – and further glutamate (Fig. 2). Oxygen free radicals gain even more significance when new oxygen reaches the damaged tissue by virtue of reperfusion, or in the penumbra where oxygen supply has not ceased entirely.

Hypoxia itself as well as the elevated intracellular concentration of calcium ions and free radicals disrupt the function

of neuronal mitochondria. Consequently, a so-called mitochondrial permeability transition pore (MPT) in the mitochondrial membrane may form. Besides impeding ATP production through loss of mitochondrial potential, the MPT leads to mitochondrial swelling, a burst of free oxygen radicals, and the release of proapoptotic molecules. Thus, a vicious cycle of further disintegration is fueled. This vicious cycle is counterbalanced in part by antioxidative enzymes like the manganese superoxide dismutase (Mn-SOD) and the cytosolic forms of the copper–zinc superoxide dismutase (CuZn-SOD). These may prevent the breakdown of the mitochondrial membrane and, thus, the release of cytochrome C, which would be the trigger of apoptosis.

5 Tissue Acidosis

In the context of stroke pathophysiology, the proton balance is intimately linked with the glucose metabolism. With reduced oxygen availability, anaerobic glycolysis, as the only remaining source of ATP production, leads to tissue acidosis. It has long been assumed that this acidosis was one of the main noxious mechanisms in ischemic stroke. This so-called ''lactate-acidosis hypothesis'' is often quoted as explanation for the ''glucose paradox'' of cerebral ischemia. This paradox refers to the observation that excessive supply of glucose, the most important source of energy of the brain, during focal cerebral ischemia does not reduce tissue damage as one should think but, instead, augments it. However, by which mechanism this happens and, in fact, whether levels of acidosis reached in brain ischemia can generate brain tissue damage at all is still far from being clear. Possibly, the pH-dependent transition of Fe(III) to Fe(II) and the release of iron from molecular storages lead to a facilitation of the Haber–Weiss reaction that forms toxic free oxygen radical species (see above). Besides the production of different species of oxygen free radicals, acidosis also interferes with intracellular protein synthesis. However, the lactate-acidosis hypothesis is not unchallenged. Particularly the fact that acidosis blocks the NMDA receptor and thus has an antiexcitotoxic effect indicates the complexity of the role that acidosis plays in cerebral ischemia.

A similarly hotly debated topic are the findings on hyperglycemia during stroke. Experimental data from animal models show a detrimental effect of hyperglycemia during focal cerebral ischemia. Clinical data also suggest that hyperglycemia during the acute phase of stroke worsens prognosis. Persisting hyperglycemia beyond the acute phase is also an independent prognostic factor for larger infarct volume and poorer functional outcome in stroke patients. It is a matter of debate whether these observations are due to a causal relationship or if hyperglycemia is a mere epiphenomenon, possibly due to a stress reaction (i.e. an effect of concomitant catecholamine and glucocorticoid release proportional to initial tissue damage). The controversial role of an associated lactate acidosis has already been discussed. An alternative concept is the glucocorticoid hypothesis. It suggests that hyperglycemia enhances the release of glucocorticoids, which are also released during ischemia in the sense of a stress reaction. Glucocorticoids have been shown to have a direct cytotoxic effect and the blockade of glucocorticoid receptors does reduce the damaging effect of hyperglycemia. On the other hand, hyperglycemia and acidosis

have a protective effect *in vitro*, and some experimental studies demonstrate that hyperglycemia can also have a beneficial effect under special circumstances.

However, a recent study on humans seems to shed light on this controversy. Perfusion and diffusion MR imaging and MR spectroscopy shows that stroke patients with hyperglycemia have a higher lactate accumulation in the penumbra. While the perfusion–diffusion mismatch (as a measure of the size relation of penumbra and core) was similar in the normoglycemic and hyperglycemic groups, the eventual infarct size and disability scores were significantly higher in the hyperglycemic group. While it could still be argued that initially hyperglycemic patients were also likely to be long-standing or latent diabetics with an overall worse microvascular state, we take this study – which links in with much of the experimental animal data – as a strong indicator for the vulnerability of the penumbra to hyperglycemia. Indirectly, it also corroborates the lactacidosis theory, which, however, still lacks direct proof.

6 Peri-infarct Depolarizations

The anoxic as well as excitotoxic depolarization of neurons and glia increases the concentration of glutamate and potassium in the ischemic core. These diffuse into the penumbral zone where they induce the electrochemical depolarization of more neuronal and glial cells that are ''just managing'' under the circumstances of oligemia. Depolarization in this context is not to be confused with short-lived action potentials, but means sustained depolarization of the entire cell membrane, a breakdown of the membrane potential that has to be actively rectified. Depolarization also causes a further significant increase in extracellular glutamate and potassium (Fig. 2). Thus, waves of sustained electrochemical depolarization spread from the core of infarction into the penumbra, bearing similarity with Leao's spreading depression. These waves are called *peri-infarct depolarizations*. Peri-infarct depolarizations occur with a frequency of 1–4/h and have been detected by functional MRI and near infrared spectroscopy. Since active rectification of the membrane potential requires energy, these peri-infarct depolarizations contribute further to the metabolic compromise and each wave turns a larger area of the penumbra toward irrevocable infarction. In addition, peri-infarct depolarizations seem to compromise the impaired microcirculation within the penumbra even further. Peri-infarct depolarizations have been detected in patients with head trauma.

7 Inflammation

The early stage of inflammation, which starts a few hours after the onset of ischemia, is characterized by the expression of adhesion molecules in the vascular endothelium as well as on circulating leukocytes. Thus, leukocytes adhere to the endothelium and transmigrate from the blood into the brain parenchyma, which is of decisive importance for stroke-induced brain inflammation (Fig. 2).

Newly expressed endothelial adhesion molecules like ICAM-1 and VCAM-1 facilitate the interaction between endothelium and leucocytes as first step of transmigration of white blood cells from blood into the tissue. They interact with the β_2-integrins CD11b/CD18 (Mac-1) and CD11a/CD18

(LFA-1) that are, in turn, expressed on leucocytes. Neutrophil granulocytes accumulate in the capillaries of the penumbra and interfere with the already impaired microcirculation. Blocking this interaction with CD18, CD11, or ICAM-1 antibodies reduces not only the number of leucocytes but also the size of infarction. ICAM-1 knockouts have also smaller infarcts than wild-type mice. Next to the β_2-integrins, other integrins that are more specific for lymphocytes like VLA-4($\alpha_4\beta_1$) come into action, too. Consequently, blocking the α_4-component reduces also the volume of infarction.

A major part in inflammation is ascribed to the population of microglial cells. These cells are the primary immunoeffectors of the CNS and make up about 20% of the entire glial mass, about the same proportion as neurons. Activation of microglia is a striking feature in the penumbra. The cells change their shape from highly ramified cells to a more plump and amoeba-like form, and they proliferate. They also express a number of characteristic surface molecules (for instance, MHCI and MHCII) and are capable of antigen presentation. Similar to leukocytes, activated microglia cells are able to produce not only a variety of proinflammatory cytokines but also cytotoxic metabolites, especially oxygen free radicals (such as peroxynitrite and superoxide) and enzymes (for instance, cathepsins). In addition, microglia is phagocytically active. The inhibition of microglial activation turns out to be protective in experimental stroke models. On the other hand, activated microglia have also been shown to release anti-inflammatory cytokines (such as TGF-β1) and growth factors. Because of the Janus-faced nature of microglial products (destructive, for example, free radicals vs protective, for example, growth factors), the overall role of microglia in cerebral ischemia is not clear at present. It is very likely that microglia play different roles at different times, with protective or regenerative activities occurring days or even weeks after the onset of ischemia.

Activated leukocytes (granulocytes, monocytes/macrophages, lymphocytes) as well as neurons and glial cells (astrocytes, microglia) produce cytokines and chemokines. In particular, proinflammatory cytokines like TNFα, IL-1, and IL-6 play a major role as mediators of the inflammatory response. They are responsible for the transition from the early, excitotoxic phase to the inflammation phase. Their regulation depends on transcription factors like NFκB, which, in turn, are activated by oxygen free radicals. Cytokine-mRNA and also the protein of TNFα and IL-1 can be detected only few hours after induction of an experimental focal ischemia. Expression of IL-6 follows only after about 24 h. These cytokines are mainly released by microglial cells and macrophages. In stroke patients, it could be shown that the intrathecal concentration of IL-1 and IL-6 correlated with the infarct size. Cytokine receptor antagonists reduce the infarct volume in animal models. For example, blockade of TNFα, by TNF-binding proteins reduces brain injury after focal cerebral ischemia. The role of TNFα is not entirely clear, however, as mice lacking the TNFα-receptor (TNFR2) have larger infarctions. In part, these contrasting results may reflect a difference in signal transduction cascades activated by the two TNFα-receptors, TNFR1 and TNFR2. It is also arguable that an increased IL-6 induction may be responsible, since IL-6 knockouts do not have smaller infarctions than their litter mates. Further to the

induction of adhesion molecules, the above-mentioned cytokines also render the blood–brain barrier more permeable and induce prothrombotic functions of the endothelium.

Not only can the proinflammatory cytokines be observed, but anti-inflammatory cytokines such as TGF-1β or IL-10 can also be induced. By downregulating the inflammation, these cytokines have a protective effect in the context of cerebral ischemia. The neuroprotective action of TGF-β1 is well known. Interestingly, this cytokine seems to play an important part in immunological tolerance. As in ischemic tolerance (see below), it is possible to induce a tolerant state toward ischemia. This protection is induced by immunogenetic proteins (for instance, myelin basic protein, MBP) and mediated by a certain lymphocyte population expressing TGF-β1. In contrast to ischemic tolerance, immunological tolerance is longer lasting. Protection lasts for months, whereas in ischemic tolerance it lasts no longer than 7 days.

Apart from cytokines, there are two other proteins that dominate the inflammatory phase: the inducible nitric oxide synthase (iNOS) and cyclooxygenase 2 (COX2). Focal cerebral ischemia models have shown that iNOS is induced on the mRNA as well as on the protein level. Protein expression reaches its height after 24 h. By inhibiting the expression of iNOS, the size of experimental infarcts can be reduced by about 30%, even if treatment is undertaken only 24 h after the onset of ischemia. Nitric oxide (NO), which is produced in much greater amounts by iNOS than by the constitutional NO synthases, acts via the formation of peroxynitrite highly cytotoxic. NO triggers apoptosis not only through peroxynitrite but also via the induction of p53, which probably causes direct DNA damage. Cox-2 is mainly generated in the penumbra. The enzyme has a destructive effect on the penumbral tissue, mainly through producing oxygen free radicals and toxic prostanoids. This seems a likely hypothesis, as both genetic and pharmacological inhibition of Cox-2 have a protective effect. Cox-2 as well as iNOS are promising targets for the treatment of stroke patients because blocking them is still effective even 6 to 24 h after ischemia.

Not only the activated residual microglia but also monocytes from the circulating blood migrate into the affected brain tissue. This transmigration is mediated by a chemokine, the monocyte-attractant protein 1 (MCP-1), which is induced 1 to 2 days after ischemia and causes immigration of monocytes. Moreover, about a third of these transmigrated cells differentiate within 14 days post stroke into microglial cells – virtually indistinguishable from autochthonous microglia. A transdifferentiation into astrocytes has also been observed, but our group has not been able to reproduce this finding. Irrespective of that, the important role of astrocytes during inflammation has been recognized, producing both proinflammatory as well as neuroprotective factors such as erythropoietin (EPO), TGF-β_1, or metallothionein 2.

In general, much further study needs to be conducted before the complex role of inflammation in cerebral ischemia is sufficiently understood to be able to specifically block the damaging proteins and foster protective elements during the inflammation process in stroke.

8 Damage to the Blood–Brain barrier

The function of the blood–brain barrier (BBB) depends on the integrity of

its cellular matrix, which consists of endothelial cells, basal lamina, and astrocytes. Cerebral ischemia causes damage to this matrix and its intercellular signal exchange. Central to these damaging processes are proteases like cathepsins, plasminogen activators, and the matrix metalloproteinases (MMP). The action of the MMPs, a group of more than 20 zinc endopeptidases, has been extensively studied. Proteolytic destruction of the basal membrane by the MMPs permits the immigration of leukocytes and promotes vasogenic edema. MMP-2 and MMP-9 are expressed within 1 to 3 h after cerebral ischemia; the level of their expression correlates with the level of BBB breakdown, the risk of hemorrhagic transformation, and the extent of eventual neuronal damage. Pharmacological inhibition of the MMPs prevents this breakdown and reduces stroke volumes. Mice with target disruption of MMP-9 are partly protected from the effects of ischemia.

Of the plasminogen activators, tissue plasminogen activator (tPA) is best known. In the brain, tPA is expressed mainly in neurons, astrocytes, and microglia. Studies of mainly primary cortex neurons have shown that tPA acts also as neurotoxin, and experiments on tPA knockouts have produced conflicting data. Since recombinant tPA is the sole licensed drug for thrombolytic therapy, these findings reflect also on current therapeutic practice. tPA has furthermore been shown to induce MMP-9 and, thus, – at least indirectly – damaging the BBB. The same holds probably for the *recombinant* tPA. This may explain why such a high number of secondary hemorrhages have been observed after thrombolytic stroke therapy. Animal experiments showed that delayed rtPA treatment – mimicking real-life delays in treatment – lead to significantly greater damage to the BBB and a major increase in mortality. The pharmacological inhibition of MMPs can reverse this effect of rtPA. In addition, tPA enhances NMDA-mediated calcium signaling and subsequent excitotoxic neuronal injury. It is a matter of controversy whether this detrimental effect is due to a cleavage of the NR1 subunit of the NMDA receptor by tPA.

The example of rtPA demonstrates once again that in order to refine treatment of ischemia, a thorough understanding of the complex mechanisms is indispensable. The development of effective and low-risk thrombolytic treatment is, of course, still one of the main objectives of pharmacological stroke research. One promising approach is the development of novel plasminogen activators, such as recombinant *desmodus rotundus* salivary plasminogen activator (DSPA-α1; Desmoteplase). Experimental evidence indicates that Desmoteplase has pharmacological and toxicological properties superior to rtPA.

9 Programmed Cell Death and Apoptosis

Apoptosis follows a similar time schedule as inflammation. It sets in after a few hours and continues over days. It is the commonest form of cell damage in the penumbra, and is very distinct from the rapid neuronal and glial death in the adjacent ischemic core, where pannecrosis is complete within few hours. In necrosis, it is the cellular edema that leads to osmolysis (see above). The released cell contents are a potent inflammatory stimulus, as discussed above.

Caspases, a group of proteases, has a pivotal role in apoptosis. They facilitate the

''orderly'' destruction of the cell, which is characterized by a condensation of both nucleus and the cell as a whole. The cell contents are fragmented into so-called apoptotic bodies. Endonucleases fragment the cell's DNA into typical strands of 180 base pair length. Other morphologic criteria of apoptosis are membrane blebbing and shrunk cytoplasm with morphologically intact organelles. While the terms ''delayed neuronal death'' (DND) and ''programmed cell death'' (PCD) are often used synonymously with ''apoptosis,'' the two former may well occur without the typical features of the latter. Although most experimental studies show some biochemical evidence for apoptosis to have taken place, histological features are often missing to substantiate the claim. This has led some researchers to question apoptosis as an actual feature of ischemia. A number of reviews have dealt extensively with the significance of apoptosis in the pathophysiology of ischemia. This is why we shall focus here on some of its mechanistic aspects in this context.

Essentially, apoptosis can be triggered in two ways, by intrinsic (i.e. basically mitochondrial) or extrinsic activation. Binding to the Fas-receptor, for example, by TNFα, triggers the extrinsic pathway. Intrinsic triggers of apoptosis in the context of ischemia are elevated concentrations of intracellular calcium, reactive oxygen species, and glutamate as well as increased DNA damage (Fig. 2). Through damage to the mitochondrial membranes, both pathways directly or indirectly lead to the activation of caspases.

The caspases are a hierarchic group of at least 14 cysteine-dependent and aspartate-specific proteases. Their inactive precursor proteins exist in every cell and can be activated through cleavage. Apoptosis is essentially an active and in itself energy-dependent cellular deconstruction process. In cerebral ischemia, the caspases 1, 3, 8, and 9 are involved, of which, the caspases 8 and 9 are the initiators of a signal cascade that activates the so-called execution caspase 3. Caspase 1 is predominantly engaged in cytokine activation. Caspase 3 is of predominant importance not only in the context of cerebral ischemia, and its genetic or pharmacological inhibition is not only in this context neuroprotective. The substrates degraded by caspase 3 are DNA repair enzymes like poly-(ADP-ribose)-polymerase (PARP) and the DNA dependent protein kinase (DNA-PK). The latter is important for the repair of double strand breaks. PARP recognizes single-strand disruptions and mediates self-repair of the DNA through swift automodification with synthesis of highly negatively charged, long, and branched ADP-ribose molecules. This process utilizes ATP and thus taps the cellular energy pool. Although not universally accepted, this ATP consumption by PARP is widely believed to be in itself cytotoxic. PARP is also capable of inducing caspase-independent cell suicide via the so-called *apoptosis-inducing factor* (AIF; see below). This also helps in explaining the partial failure of caspase inhibitors in some models of cerebral ischemia. The genetic or pharmacological blockade of PARP has, however, been demonstrated to be neuroprotective in experimental stroke. Of significance is the cleavage by caspase 3 of the inhibitor of caspase-activated DNase (ICAD). ICAD is thus activated and causes the characteristic feature of ''laddering'' that has been described in all stroke models. The term laddering draws on the regular appearance of those DNA fragments as ladderlike bands on a gel electrophoretic separation. The length of the resulting DNA fragments

reflects the complex structure of eukaryotic genetic information in the chromatin. Chromatin is a structure, in which most of the DNA is enclosed by specific proteins, the histones (see epigenetics), leaving only few positions accessible for endonucleases. Complete apoptotic laddering leaves DNA-oligomers of about 140 to 180 base pairs in length, which do no longer contain any useful genetic information. Apart from destroying genetic information, caspases also degrade structure proteins of the nucleus and cell, such as laminin, actin, and gelsolin.

Cytochrome C is not only an essential part of the mitochondrial electron transfer chain and hence for the energy production in the cell but also a crucial mediator in the caspase activation cascade. On the extrinsic pathway of apoptosis, stimulation of the Fas-receptor leads to the formation of the ''death-inducing signaling complex'' (DISC). DISC activates caspase 8 from its precursor protein, which, in turn, activates Bid, a proapoptotic protein of the Bcl-2 family (see below). Bid then induces the liberation of cytochrome C from the mitochondrial membrane. Other members of the proapoptotic Bcl-2 family are Bad and Bax, important on the intrinsic pathway. Their activation leads to their translocation into the outer mitochondrial membrane and to the establishment of the mitochondrial permeability transition pore (MPTP), leading to the release of cytochrome C. Another way of its release from mitochondria is obviously direct membrane damage by free radicals. Cytochrome C, together with the cytosolic protein Apaf-1, forms the caspase precursor protein, and, using ATP, the so-called apoptosome. The apoptosome activates caspase 9 through cleavage from its precursor. Whether cytochrome C is eventually released depends, however, on the balance of proapoptotic members of the Bcl-2 family like Bid, Bax, Bad, and Bag, and their antiapoptotic counterparts Bcl-2 and Bcl-x_L. Prevailing expression of Bcl-2 and Bcl-x_L results in clearly smaller infarction after focal cerebral ischemia. Treatment with a Bcl-x_L fusion protein containing the TAT domain of the human immunodeficiency virus (HIV) for cell penetration acts also neuroprotectively in models of ischemia. Bcl-2 and Bcl-x_L seem to have a stabilizing effect on the mitochondrial membrane; they prevent the formation of MPTP, the ensuing cytochrome C liberation, and the formation of AIF. Not only the reinforcement of antiapoptotic factors but also the attenuation of proapoptotic proteins may be neuroprotective in cerebral ischemia. For instance, the phosphorylation of Bad leads to its sequestration by the protein 14-3-3 and thereby to its inactivation. The PI3K/Akt-pathway, utilized by many neurotrophic factors such as erythropoietin (see below: endogenous neuroprotection), plays an essential role in this. It has been reported that Akt has been activated during cerebral ischemia. Whether this has a functional impact in stroke remains unclear at the moment.

Other important protein groups involved in stroke are the members of the IAP-group (inhibitors of apoptosis proteins). The overexpression of the X-chromosome-linked IAP (XIAP) has been shown to be protective in stroke models. IAPs act either indirectly by inhibiting the apoptosome or directly inhibiting caspase 3, but can themselves be blocked by other proteins such as DIABLO (in mice, the human homologue is Smac) that is physiologically localized in mitochondria. DIABLO is released after focal ischemia and binds to XIAP. It is yet unclear what its function is during focal ischemia. The data discussed show, however, that apoptosis underlies

a complex regulation process that is controlled at many levels.

10 Ischemia-induced DNA Damage, DNA Repair, and p53 as Genotoxic Sensor

The emergence of DNA damage and its repair functions in the context of focal cerebral ischemia are particularly interesting. DNA damage is caused by oxygen free radicals (see above). Particularly, the interaction of hydroxyl radicals with DNA results in strand breaks and base alterations. Hydroxyl radicals have a very short half-life – with the exception of peroxynitrite, formed from NO and superoxide – and are unlikely to reach the nuclear DNA from outside the cell. They are more likely to be produced in close proximity to the nucleus as a homolytic cleavage product of peroxynitrite, which has the ability to diffuse over longer distances.

Under physiological circumstances, DNA lesions are generated with a frequency of about 10 000 events per cell each day. They are recognized and repaired efficiently, provided the repair enzymes are intact and not overloaded. In the wake of ischemia and reperfusion, the tissue is flooded with oxygen free radicals, causing abundant DNA damage. Alterations that are typically caused by free radicals have been found in the mouse model of transient focal ischemia, where a massive increase in DNA damage was observed 10 to 20 min after reperfusion. Foremost, 8-hydroxy-deoxy guanosine becomes much more prevalent in both nuclear as well as mitochondrial DNA after ischemia. These alterations are repaired partially within 4 to 6 h, and the increase in repair activity is proportional to the degree of DNA damage.

There are three basic DNA repair mechanisms – base excision repair (BER), nucleotide excision repair (NER), and what is known as mismatch repair. BER seems to be of particular significance in ischemia. During BER, DNA glycosylases excise damaged or modified bases. The thus generated purine and pyrimidine-free sites (AP-sites) are eliminated from the damaged DNA strand by AP-endonucleases (apurinic/apyrimidinic endonucleases) and replaced by DNA polymerase β and DNA ligase with a short strand of 1 to 4 nucleotides based on the complementary blueprint of the remaining undamaged strand.

Apart from oxidative DNA damage, deamination of cytosine may produce uracil. In BER, such alterations are sorted out by uracil-DNA-glycosylase (UDG). We found that knockout mice deficient in UDG have substantially larger infarctions than the wild-type controls.

DNA repair is neither inexhaustible nor infallible. Persisting mutations are the result of erroneous DNA repair. In models of transient focal ischemia, a dramatic increase in the frequency of mutations has been observed. Half of them were transitions and transversions. The other half were deletions and occasional insertions, mostly resulting in a frame shift (frame shift mutations) of the open reading frame (ORF). It seems that not only the exhaustion of the repair capacity but also an impaired proofreading ability in the exonuclease-negative DNA polymerase β expressed in the brain is to blame for these mutations. The major role of DNA repair is to ensure transcription of mRNA from intact genes. An obvious consequence of mutations is instability of the genetic information that may lead to faulty proteins, eventually resulting in

either cellular malfunction, disintegration, or spawning of tumors.

The maintenance of swift and effective DNA repair is therefore essential in postmitotic cells like neurons. In order to adapt to an increased demand, a cell may try to increase its repair efficiency. Apoptosis is another way of avoiding erroneous protein synthesis and the potential emergence of tumors (see above). Both mechanisms are found in focal cerebral ischemia, and it seems to be the extent of the damage that determines which scenario will prevail.

We have several reasons to believe that the tumor suppressor protein p53 represents the molecular switch on the crossroads of attempted repair and apoptosis. (1) p53 is mainly induced by DNA damage; (2) p53 can halt the cell cycle, and thus prevent the division of non-neuronal cells before complete repair; (3) p53 can induce apoptosis if the damage is extensive. In most models of ischemia, it could be shown that p53 had been induced. The fact that p53 knockouts have significantly lower infarct volumes accords with p53's proapoptotic function. However, it seems paradoxical that heterozygous $p53^{+/-}$ mice show even smaller infarctions. An attenuated expression of p53 seems to give better neuroprotection than a total lack of it, which hints at the dual function of the gene. It would be interesting to find out if longer-term neoplasias could be the downside of this short-term effect.

11 Epigenetic Mechanisms

Experimental work of the last years has shown that, apart from DNA repair, epigenetic mechanisms like DNA methylation and histone modification also play an important role in ischemic stroke. The transcriptional gene expression is not only regulated by transcription factors but also depends on epigenetic mechanisms that mainly modify the chromatin structure.

In the mammalian genome, DNA methylation is a covalent, postreplicative modification at the carbon 5 position of the pyrimidine ring of cytosine bases (m^5C); it typically occurs in CpG dinucleotides. DNA methylation is catalyzed by DNA methyltransferases (DNMT1, DNMT3a, DNMT3b). The main function of DNA methylation lies in the regulation of gene transcription. Methylated genes are barred from expression in a process called "gene silencing." First of all, many transcription activators are unable to bind to methylated loci at all. Furthermore, there is a group of methyl-CpG-binding domain proteins (MBD) that form a complex with histone deacetylases (HDAC), which, in turn, by deacetylation of histones, cause the chromatin structure to condense. Through this condensation, the gene-regulatory loci become inaccessible for transcription factors. Five proteins of the MBD family are known to date: MBD1 through 4 and MeCP2. HDACs deacetylate predominantly histones H3 and H4. Conversely, acetylated histones open up the chromatin structure, permitting the gene-regulatory regions (promoters, enhancers) to become active again, and, ultimately, enabling gene transcription through binding of transcriptional activator proteins. While the state of deacetylation or acetylation of a CpG hypomethylated promoter or enhancer region is comparatively volatile, DNA hypermethylation of these regulatory regions results in a more stable repression.

Initially, DNA methylation was thought to be of biological significance only for fundamental phenomena of cell biology like embryogenesis and differentiation,

in X-chromosome inactivation, genomic imprinting, and in several neoplastic diseases. In more recent years, its pathophysiological role in a number of further conditions has been recognized, such as Fragile-X syndrome, ICF (*I*mmunodeficiency, *C*entromere instability, *F*acial anomalies) syndrome, or Rett syndrome.

For the first time, we were able to detect the involvement of DNA methyltransferase 1 and DNA methylation in an acute disease, such as ischemic stroke. In addition, a complex pattern of an altered expression of MBD-family proteins has been described in a model of transient cerebral ischemia. The inhibition of DNA methylation had a protective effect, as had manipulations to the acetylation state of histones. Pharmacological inhibition of a histone acetyltransferase with trichostatin A (TSA) caused enhanced histone acetylation *in vitro* as well as *in vivo*, and proved to be neuroprotective. A similar effect was shown recently in a mouse model of Huntington's disease. Thus, the epigenetic mechanisms of gene regulation may provide yet another axis of neuroprotective therapeutic intervention.

12 Gene Expression

The role of transcription factors such as AP-1, HIF-1, and NF-κB in the context of cerebral ischemia has been recognized for much longer. They initiate the transcriptional activation of complex programs of gene expression. The whole hierarchical system of such programs has been unraveled over more than 15 years. Within few hours, the transcription of immediate early genes such as c-fos is activated. Some of these, in turn, form transcription factors such as AP-1. They induce a variety of genes that may have protective or destructive effects. Cells that survive the ensuing biochemical negotiation finally express genes that contribute to a structural reorganization and thus to greater plasticity. A great many of the genes involved have been subject to pathophysiological studies in stroke. Their functional significance has been studied either in descriptive ways, that is, by describing candidate genes on RNA or protein level or using transgenic technology. Especially knockout mice have been extremely useful for this approach. The genetic elimination of specific proteins in mice used for these experiments has been particularly enlightening for the untangling of the signaling cascades involved in and after stroke.

In recent years, the advent of genetic screening methods has allowed for the systematic investigation of complex gene expression programs that are initiated by cerebral ischemia. In contrast to candidate-gene research, they permit a more unbiased approach. They are based on the assumption that focal cerebral ischemia does incite complex changes of gene expression. Not just a single, specifically targeted gene is examined for its role in the scenario of stroke but – ideally – all genes. For this new research, paradigm terms have been coined like discovery science, genomics, transcriptomics, proteomics, and cellomics. So-called high-throughput technologies as well as a highly evolved bioinformatic methodology are a prerequisite for acquiring and managing the vast bulk of information involved. DNA micro arrays or SAGE technology facilitate the examination of global changes in gene expression on mRNA level (transcriptomics). Global changes on the level of protein synthesis can be described with a combination of two-dimensional gel electrophoresis and identification techniques

(proteomics). The first results of a number of studies using these techniques in the context of cerebral ischemia are now available.

What do these results imply? First of all, they confirm that the assumption of the existence of complex stroke-induced programs of gene expression is correct. Secondly, they demonstrate that they follow a robust temporal and spatial pattern. Not only do the expression patterns differ between core and penumbra but also within the penumbra there are many spatial and temporal differentiations. This has even given rise to a concept of ''multiple penumbras.'' Thirdly, this approach has not only confirmed many findings of candidate gene research but also underpinned our pathophysiological understanding. Thus, a number of heat shock proteins, antioxidative enzymes, growth factors, and pro- as well as anti-inflammatory proteins have been detected. Not just transcription factors, but a variety of proteins have been found to play essential roles in the metabolism of RNA and DNA. Finally, proteins that contribute to structural and functional reorganization are thought to establish the molecular base of the functional healing potential after strokes. Not surprisingly, a number of hitherto unidentified genes have been brought forth by discovery science.

Although the results of these screening methods give a great boost to stroke research and open doors to new insights, a full functional characterization of the differentially expressed genes will take many more years. Our understanding of the emerging network of gene expression increasingly depends on not only biological but also mathematical models. However, there are things we do know already; for instance, that protein modifications are of great functional importance. Thus, the functional value of numerous proteins depends on their phosphorylation state. For example, the specific phosphorylation of the usually proapoptotic protein Bad prevents apoptosis in the ischemic penumbra. The differential function equals thus not simply differential gene expression, and genetic screening methods will never be sufficient to paint the full picture of stroke-induced molecular pathways. The same holds for proteomics, which, just like transcriptomics, neglects the functional importance of RNAs that do not code for proteins.

These molecular pathways, however, potentially lead to new, neuroprotective therapies and open up new perspectives for fundamental issues like neuronal plasticity and stem cell research.

13 Cell Replacement

In recent years, it has been shown in different models that ischemic brain injury induces neuron formation from neuronal stem cells. Such cells reside in the subgranular zone of the dentate gyrus, in the subventricular zone below the lateral ventricles, and periventricularly in the hippocampus. They can migrate into parts of ischemic lesions within the striatum, the dentate nucleus, and the hippocampal CA1 region. It is still a matter of debate as to what extent a similar neuroneogenesis also takes place within the penumbra in cortical regions. Neither is it entirely understood to what extent these migrating cells, which doubtlessly express neuronal markers, become functional. Observations so far indicate that it is not a very effective process and that most of the migrating cells perish. However, if these neuronal cells could be enabled or encouraged to

assume the function of damaged neurons, this would imply another new therapeutic paradigm. Indeed, intrathecal infusion of growth factors like FGF-2 and EGF after global cerebral ischemia did not only stimulate the migration and the survival of these cells but also resulted in improved functional results both on a cellular and on a neurobehavioral level. Astrocytes are newly formed in a similar fashion. For future therapeutic evaluation, it should be kept in mind not only that growth factors such as erythropoietin, FGF-2, EGF, VEGF, SCF, and BDNF have this beneficial effect but also that their expression depends on the stimulation of the NMDA receptor by glutamate. A pharmacological blockade of this receptor with the intention of inducing neuroprotection could interfere with this effect and thus be counterproductive. This is yet another example of an incomplete understanding of the signaling mechanisms, leading to a paradox in the interpretation of our neuroprotective data. Bearing this in mind, it is needless to say that the ongoing experimental studies of cell replacement are still far from clinical implementation. However, the available experimental observations are very exciting: For instance, neural and also haematopoietic pluripotent cells differentiate into neuronal and glial cells when injected into infarction sites. On the other hand, this potentially helpful strategy may have detrimental effects too. In a mouse model of stroke, for example, murine embryonic stem cells did not migrate into the damaged tissue, but produced highly malignant teratocarcinomas at the site of implantation, independent of whether or not they had been predifferentiated *in vitro* into neural progenitor cells. As far as safety is concerned, an endogenous pathway of cell regeneration may be more promising. Bone marrow–derived cells (BMDC) introduced into the brain possess a differentiation potential capable not only of forming microglia but also neurons. This apparent plasticity has been attributed to transdifferentiation. However, more recent data suggest, in the case of neurons, that BMDCs do not differentiate into but rather fuse with Purkinje cells in the brain. These observations suggest that cell fusion contributes to the maintenance of neurons. One potential use for haematopoietic cells migrating from blood into ischemic brain tissue could be the therapeutic transfer of protective gene products such as growth factors.

14 Endogenous Neuroprotection – Ischemic Tolerance

In the wake of ischemic stroke, not only cascades of destruction are induced but also endogenous protective mechanisms are activated. These mechanisms are currently studied intensively. Central to this research are models of ischemic preconditioning. The idea behind ischemic preconditioning is to achieve a protected state of a cell, tissue, or whole organism by subliminal exposure to a noxious stimulus (trigger), which is applied just below the level at which damage would occur. The stimulus induces a protective state against insults that would normally be lethal. Subliminal ischemia ('ischemic tolerance'), hypoxia, reactive oxygen free radicals, inflammation, and so on can serve as tolerance-inducing stimuli. After induction, there are two time windows within which ischemic tolerance can be observed. Early tolerance occurs after about 5 to 120 min following stimulation (classical preconditioning), while delayed preconditioning sets in after a latency of about

24 to 72 h. Seven days after induction, the state of protection is no longer detectable. Studies of patients who had transient ischemic attacks (TIA) before suffering a persistent stroke indicate that ischemic tolerance may also exist in humans. Subsequent to a TIA, brain infarcts were smaller in comparison with patients without preceding TIA. As a TIA, by definition, does not lead to infarction, it may thus be considered as a stimulus that induces tolerance.

Unlike severe ischemia, leading to stroke, a preconditioning stimulus induces exclusively protective, but not destructive, signaling cascades. There are basically three stages of protective signaling that can be distinguished in delayed preconditioning. In the *induction phase*, molecular sensors (mostly receptors, channels, and regulators) are activated by transcription factors. During the *transduction phase*, certain protein kinases, transcription factors, and paracrine and autocrine mediators, such as growth factors, amplify the signal and thereby prepare the *effector phase*. In this phase, proteins with a direct protective impact (antiapoptotic, anti-inflammatory, antioxidative) are switched on. These mechanisms are the molecular basis for ischemic tolerance and have been reviewed in detail elsewhere. Here, we want to give only a brief outline of the concept. On the basis of animal models in mice and rats as well as cell culture experiments, we were able to describe the following signaling cascade: In astrocytes, a tolerance-inducing hypoxic stimulus induces the transcription factor HIF-1 (hypoxia-inducible-factor-1). HIF-1 is one of the central sensors of hypoxia and induces the expression of erythropoietin (Epo). Erythropoietin is released by astrocytes and binds to the neuronal Epo receptor. Via the activation of a protein kinase cascade, Epo prevents apoptosis, as shown in Fig. 3. This neuroprotective signaling cascade mediates approximately 50% of the protection observed in our model. The remaining 50% of protection that it does not account for suggests the presence of further mechanisms in ischemic preconditioning. As a matter of fact, beside this paracrine cascade, which is mediated by astrocytes and neurons, a number of other mechanisms have been described. A host of antiexcitotoxic, anti-inflammatory and antiapoptotic mechanisms, including programs for regeneration and repair, have been implicated so far (Fig. 4).

Understanding these mechanisms may enable us in the future to induce or boost endogenous protection in patients as a novel strategy to safeguard the brain against hypoxic/ischemic damage. For example, Epo is a promising drug in stroke therapy. There is solid evidence that exogenously applied Epo is neuroprotective *in vivo* and *in vitro* models of cerebral ischemia. Clinical phase I and II trials suggest that Epo is not only safe but also beneficial in the therapy for acute stroke. In addition, pharmacological inducers of ischemic tolerance in brain could become a promising tool in circumstances when ischemia can be anticipated, for example, before cardiac or carotid surgery. For example, desferrioxamine, an approved drug for the treatment of hemosiderosis, induces robust ischemic tolerance by inducing erythropoietin in an HIF-1-dependent manner.

Combined, the above-mentioned results demonstrate that brain cells are not only challenged by deleterious mechanisms but also activate innate programs to protect themselves from ischemia. However, cerebral ischemia does not only affect the brain

15
Stroke-induced Immune Depression (SIDS)

Within three days after stroke, up to 61% of the stroke patients develop fever. Findings from animal experiments show that pyrexia of more than 1 °C does not only lead to a dramatic increase of the cytotoxic neurotransmitter glutamate but also to a significantly larger volume of the infarction. Clinical trials demonstrated that both mortality and morbidity rise with the occurrence of fever in stroke. The most common cause of fever in the acute course of stroke is infection. Infectious complications occur in 21 to 65% of stroke patients. Pneumonia is the most frequent

Fig. 3 Epo-mediated endogenous neuroprotection (a) The transcriptional activator protein HIF-1 functions as a global regulator of oxygen homeostasis that facilitates both oxygen delivery and adaptation to oxygen deprivation. HIF-1 consists of two subunits, HIF-1α and HIF-1β. The HIF-1ß subunit is constitutively expressed, whereas the HIF-1α subunit is precisely regulated by the cellular oxygen concentration. Most relevant is the regulation of HIF-1α steady state protein levels. Under normoxic conditions, HIF-1α is rapidly hydroxylated by prolyl hydroxylase domain containing protein (PHD), subsequently ubiquitinated and degraded through a proteasomal pathway. Since oxygen is rate limiting for PH activity, hypoxia inhibits HIF-1α degradation and HIF-1α can heterodimerize with HIF-1ß. After dimerization, HIF-1 enters the nucleus, binds to its recognition site 5′-RCGTG-3′ in the hypoxia response element, and recruits coactivators as well as basal transcription factors. This transcription complex initiates the gene expression that mediates response to hypoxia. More than 40 HIF-1 target genes are known. One of them is Epo, a glycoprotein hormone that regulates hematopoiesis by promoting cell survival, proliferation, and differentiation of immature erythroid cells. Although Epo is mainly expressed in adult kidney and fetal liver tissue, it is also found in the brain. In ischemic preconditioning, low oxygen tension (hypoxia) induces Epo in astrocytes, depending on HIF-1. Epo is a key mediator of paracrine neuroprotection from astrocytes to neurons, which acts via its cognate receptor. (b) Epo exerts its neuroprotective effect by preventing neuronal apoptosis. The intracellular molecular pathways of Epo-induced neuroprotection involve tyrosine phosphorylation. Rather than containing an intrinsic protein tyrosine kinase activity, the relatively short cytoplasmatic domain of the Epo receptor (EpoR) interacts with nonreceptor tyrosine kinases. A key molecule is the janus kinase 2 (JAK2), which is constitutively associated with EpoR. The first step of this intracellular signaling is Epo-induced homodimerization of EpoR. Homodimerization of EpoR induces a conformational change of the whole protein complex, which place JAK2 in close proximity to EpoR, thus promoting transtyrosine phosphorylation and activation of JAK2. JAK2 induces phosphorylation of cytosolic tyrosines in the EpoR. This allows docking to the EpoR cytosolic domain of several signaling proteins, including phosphatidyl-inositol 3-kinase (PI3K) and Signal transducer and activator of transcription proteins (STAT1, STAT3, STAT5). These proteins, in turn, become tyrosine phosphorylated and thus activated. PI3K suppresses apoptotic cell death through its downstream effector protein kinase B (PKB)/Akt. Activated Akt kinase suppresses apoptosis by phosphorylation of the proapoptotic Bcl2-family protein Bad. Phosphorylated Bad prevents apoptosis, since unphosphorylated Bad is capable of forming heterodimers with the antiapoptotic proteins Bcl-X_L or Bcl-2 and thereby antagonizes their antiapoptotic function. STATs exert their antiapoptotic effects by transcriptional activation of antiapoptotic proteins from the bcl-2 gene family, in particular, bcl-2 and bcl-X_L. Activation of transcription factor NF-κB, a key event for ischemic preconditioning, is activated by phosphorylation of its inhibitor subunit IkappaB. NF-κB induces the expression of the inhibitor of apoptosis proteins cIAP2 and XIAP. Activating these three signaling pathways, Epo induces a fast and long-lasting neuroprotection by upregulation of antiapoptotic as well as downregulation of proapoptotic proteins.

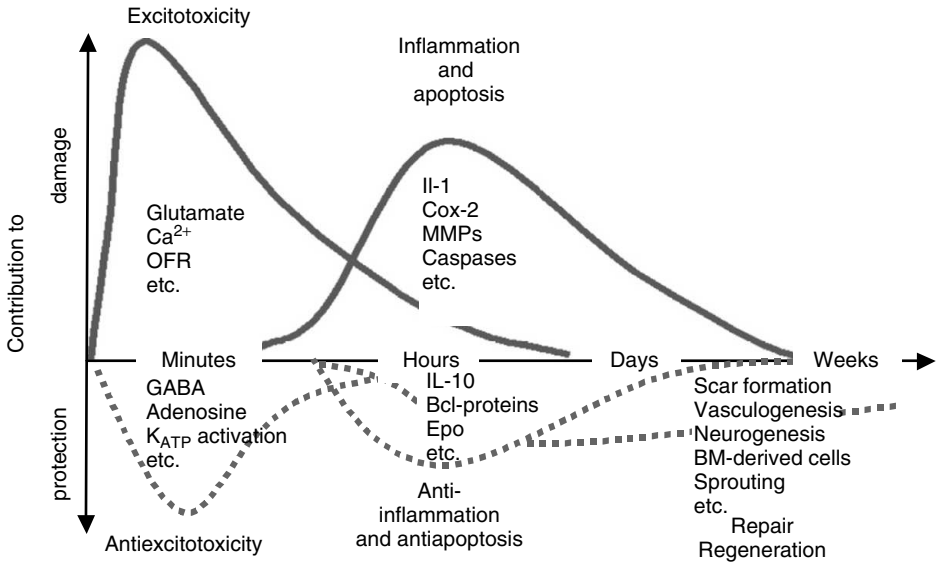

Fig. 4 Cell death–inducing and endogenous neuroprotective mechanisms in cerebral ischemia. Focal cerebral ischemia induces a complex series of mechanisms that damage brain cells. Brain tissue responds to most of the listed examples of noxious signals by inducing protective mechanisms. In infarcted tissue, destruction has overwhelmed protection, although tissue around the ischemic core might have been spared by restored substrate delivery (owing to delivery to collaterals, spontaneous or therapeutic reperfusion, or vasculogenesis) and cellular mechanisms of protection. In this cartoon, the *x*-axis reflects the evolution of the cascades over time and the *y*-axis illustrates the impact of each element of the destructive (top) and protective (bottom) cascades on the final outcome. The red dotted lines envelop major pathophysiological entities of tissue destruction in stroke (grouped for the acute mechanisms of excitotoxicity and the delayed mechanisms of inflammation and apoptosis) and the green broken lines envelop corresponding protective tissue responses. Abbreviations: BM, bone marrow; Cox-2, cyclooxygenase 2; Epo, erythropoietin; IL, interleukin; MMPs, matrix metalloproteinase; OFR, oxygen free radicals (Reprinted from Dirnagl, U., Simon, R.P., Hallenbeck, J.M. infection in stroke patients and a major mortality risk factor.

Stroke patients have a much higher risk of developing severe bacterial infections. It is obvious that factors such as immobilization, reduced bulbar reflexes, drowsiness, and, subsequently, a higher risk of aspiration promote pulmonary infections. Although these are risk factors for bacterial infection, they cannot fully explain the high risk of infection observed. A large meta-analysis showed that other factors had to be equally important. In particular, a reduced function of the immune system was postulated. Very recently, we were able to prove that immunodepression following stroke causes severe bacterial infections. In a mouse model, we demonstrated that, three days after stroke, severe bacterial infections (mostly pneumonia and sepsis) develop spontaneously. Stroke induces an overactivation of the sympathetic nervous system and leads to a rapid, severe, and sustained lymphopenia as well

as to a disturbed function of lymphocytes and monocytes. Interestingly, there is also evidence for an overactivation of the sympathetic nervous system within the first two days after stroke in humans. Furthermore, we were able to show that a disturbed secretion of interferon-γ from T cells and NK cells is central to these severe infections. Both a cellular reconstitution of the immune system and the application of interferon-γ prevented infections. In addition, pharmacological inhibition of the sympathetic nervous system with the β-receptor-blocker propranolol not only prevented infections but also dramatically reduced the high rate of mortality in this model. Our studies are the first to provide a mechanistic explanation for the clinical phenomenon of increased susceptibility to infections after stroke.

Approaches to prevent infection after stroke seem to be desirable. Preventive anti-infective therapy is expected to reduce a number of negative prognostic factors such as fever, infection-induced arterial hypotension, and the systemic release of proinflammatory cytokines. In addition, with the prevention of severe infections, an earlier mobilization and rehabilitation becomes feasible. In an experimental stroke model, we were able to demonstrate that preventive anti-infective therapy with an antibiotic after focal cerebral ischemia not only reduces mortality and the infarct sizes but also decreases the functional deficit. These experimental results lead to the initiation of a Phase IIb trial for preventive antibacterial short-term therapy in patients with acute ischemic media infarction (Preventive AN*ti-infective* THER*apy* I*n* S*troke*; PANTHERIS, Berlin). Other groups initiated similar trials (A. Chamorro, Spain; M. Hennerici, Germany; personal communications).

16 Perspectives

Owing to intensive experimental and clinical research, our pathophysiological understanding of cerebral ischemia has greatly improved over the last 15 years. Complex pathways involving excitotoxicity, oxidative and nitrosative stress, periinfarct depolarizations, inflammation, and apoptosis-like mechanisms have been described in cell culture as well as animal models of cerebral ischemia. Despite impressive results in animal experiments on neuroprotection, the transfer of preclinical results into human stroke therapy has been so far unsuccessful. Possible reasons for this dilemma include problems with the models used, the design of the clinical trials as well as the drugs, and they have been discussed intensively. However, we believe that although we have often not been able to transfer our experimental results into human stroke therapy, some cautious optimism is justified. More and more experimental data demonstrate that the division of molecular mechanisms in ''good'' and ''bad guys'' is an improper simplification, and we need to gather more data in order to identify more suitable molecular targets. Since in stroke there are multiple pathways that cause cell death, it seems reasonable to develop combination therapies targeting all these mechanisms. In addition, the advances in understanding endogenous neuroprotective mechanisms provide new therapeutic options to improve tissue survival after stroke. Targeting systemic complications like severe bacterial infections in a preventive manner may also improve outcome. Thus, an ever more refined understanding of complex damaging cascades as well as the development of more complex therapeutic strategies will

continue to be the basis for more successful therapies of stroke in the future.

Keywords

Acceptor Molecule
A molecule, usually a macromolecule that has the potential of binding to specific peptides, or ligands.

Amino Acid
The smallest subunit of protein, having an amino, a carboxyl, and a side-chain functional group.

Combinatorial Peptide Library
A large collection of different peptides, with many possible combinations of amino acids joined together.

Combinatorial Nonpeptide Oligomer Library
A large collection of different oligomers, with many possible combinations of non-amino acid subunits joined together.

Combinatorial Small Molecule Library
A large collection of different small molecules, with many possible combinations of small, organic moieties joined together.

Motif
A pattern of amino acid sequences that interact specifically with an acceptor molecule.

Peptide
A polymeric compound formed by the condensation of two or more amino acids; here we refer to compound less than 20 amino acids long.

The field of combinatorial peptide chemistry was created when the first limited peptide library was synthesized with multipin technology in 1984. Since 1990, the field of combinatorial chemistry has advanced rapidly. It has emerged as a powerful tool in the study of many biological systems. In essence, a combinatorial peptide library (numbering 10^4–10^8 different molecules) is chemically synthesized and subjected to screening for biological activity. Such screening allows for the rapid discovery of peptide ligands with biological interest. The amino acid sequence of an ''active'' peptide is then determined. Other biologic peptide libraries, such as those involving filamentous phage-display peptides, can typically accommodate only the 20 natural amino acids. In contrast, synthetic peptide libraries have the potential to incorporate D-amino acids and other unnatural amino acids, as well as specific secondary structures or scaffolding structures that may enhance biologic activity. In addition to amino acids, biological subunits such as monosaccharides, nucleotides,

lipids, or even small organic moieties can be used. The advent of these peptide, nonpeptide oligomer, or small molecule library methods not only facilitates the drug discovery process but also provides important information for the fundamental understanding of molecular recognition.

1 Principles

1.1 Random Combinatorial Libraries

The traditional drug discovery process relies heavily on random screening of plant and animal extracts, fermentation broths, and synthetic compounds, individually or in mixtures. The process is often laborious, expensive, and time consuming. And even after an active mixture has been detected, a tedious process of purification and structure determination is still required. Once a drug lead has been identified, additional studies on the structure-activity relationship of individual synthetic analogues of the parent compound often are necessary for the optimization of the drug. The random combinatorial library synthesis and screening methods can speed up the drug discovery process. Notably, this method can accommodate much larger numbers of candidate molecules. Fig. 1 gives the number of possible permutations in a random peptide library when 20 eukaryotic amino acids are used in each coupling cycle. For example, there are 1.28×10^9 possible permutations for a random heptapeptide. The number of peptides present in a library ranges from a thousand to as many as 100 million, depending on the method used. In general, the methods of generating a combinatorial library can be categorized into two approaches: the synthetic approach and the biological approach.

1.2 Synthetic Peptide Libraries, Synthesis and Screening

Most of the synthetic peptide libraries are synthesized on a solid-phase support system, such as a polystyrene resin bead, using either the Fmoc/*t*-But (9-fluorenylmethoxycarbonyl/*tert*-butyl) or *t*-Boc/Bn (*tert*-butoxycarbonyl/benzyl) amino acid protection strategies. However, hydrofluoric acid (HF) is required to cleave off the side-chain protecting groups for the *t*-Boc/Bn chemistry. Since HF is highly toxic, requires a special apparatus, and partially degrades the polyethyleneglycol (PEG) chain on the resin, the Fmoc/*t*-But strategy is preferable for the synthesis

of peptide libraries. By using three- to four-fold excess of activated amino acids, the yield of each coupling cycle is usually in excess of 99%. Occasionally, double coupling may be needed if the first coupling cycle is not complete. In general, there are two methods of synthesizing a random library: the ''split-mix synthesis'' method (Fig. 2) and the ''mixed synthesis'' method. In 1991, Furka et al., Houghten et al. and Lam et al. described the ''split-mix synthesis'' method, in which the resin beads are split into several equal aliquots, followed by coupling of each activated amino acid separately with each individual resin aliquot. The reactions are driven to completion as monitored by the ninhydrin test, and then the resins are mixed and washed, and the N_α-amino groups are deprotected, washed, and split into several equal aliquots again. The process is repeated for multiple cycles until the desired peptide length has been attained. In the ''mixed synthesis,'' all the N_α-protected amino acids, which are usually concentration adjusted according to predetermined reactive rates and are added concurrently to the resin. It has been claimed that almost equimolar ratio mixtures of individual peptides can be obtained with this method.

Peptide libraries can contain linear or cyclic structures. Linear peptides usually are very flexible. In certain cases, one may prefer a more rigid or constrained conformation, such as a cyclic structure, to enhance biologic activity. Cyclization of these synthetic peptide libraries can be accomplished by disulfide formation, β-lactam formation, thioether bond formation, alkylation, or metal chelation. For example, side chains of cysteine, homocysteine or penicillamine can be used for disulfide formation. Side chains

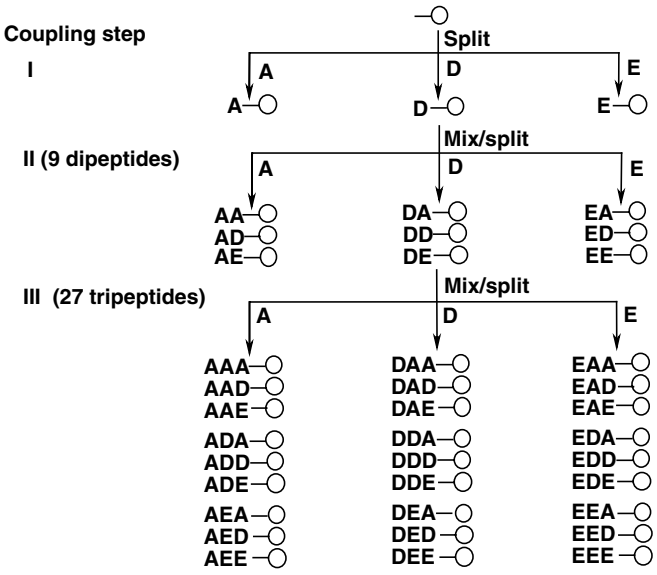

Fig. 2 Synthetic scheme of the ''split-mix synthesis'' method to generate a one-bead one-compound combinatorial library. A, D, and E are building blocks (in this case amino acids). The circles represent the resin beads.

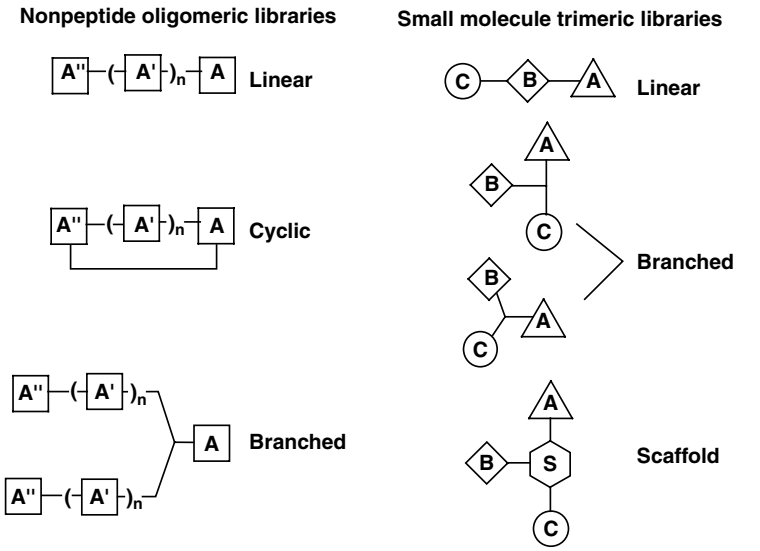
of lysine or ornithine and aspartic acid or glutamic acid can be used for β-lactam formation. γ-carboxylglutamic acid side chains can be used for Ca^{2+} chelation, and histidine side chains for Ni^{2+} or Zn^{2+} chelation. Proline (L- or D-enantiomers) or other amino acids able to mimic turns (e.g. (3S,6S,9R)-2-Oxo-3-amino-7-thia-1-azabicyclo[4.3.0]nonane-9-carboxylic acid, a commercially available β-turn inducing amino acid) have also been placed in the middle of a peptide to promote a turn structure. When synthetic peptide chemistry is used, natural amino acids and their D-enantiomers, unnatural amino acids including non-α amino acids (e.g. β- or γ-amino acids), amino acid derivatives from side-chain derivatization, and *N*-methylated amino acids can be incorporated into the peptide libraries. In addition, amino acids with saccharide or nucleotide side chains can be used to introduce carbohydrate or nucleic acid features into the random libraries. Furthermore, compounds with reduced peptide bonds can be constructed. In some cases, an *N*-acetylated peptide library may be preferred.

An important feature for the effective use of a peptide library is the screening method. When the peptide library has been synthesized, the solid-phase bound peptides, such as the ''one-bead one-compound'' (OBOC) combinatorial library generated by ''split-mix synthesis'' (Fig. 2), can then be screened directly in an ultra high-throughput manner. Millions of peptides can be screened in parallel for a specific acceptor molecule (receptor, antibody, enzyme, virus, whole cell, etc.) within a day or two concurrently, and only small amount of acceptor is required. With various screening techniques, compound beads with a specific biological, chemical, or physical property can be rapidly identified. Direct binding assays have been commonly used to screen the solid-phase bound peptide library. These peptides are often covalently linked to the solid support. Detection is usually accomplished by an enzyme-linked assay, fluorescent assay, or radionuclide assay. Direct functional assays have also been developed including covalent modification of peptide beads by enzymes (e.g. phosphorylation by protein kinases with [γ-^{32}P]ATP) and proteolytic cleavage of bead-bound peptide by proteases.

In some peptide library methods, the peptides can also be cleaved off the solid support and screened by a solution-phase assay if a cleavable linker is used. The major advantage of this approach is that various standardized receptor-binding, biochemical, or cellular assays can easily be adapted for screening. Purified acceptor molecules are often not needed, and a biochemical or biologic end point may sometimes be measured even if the molecular target is unknown. However, the solution-phase assay, in general, is more time consuming, and some of the ligands may be insoluble in the assay buffer and therefore not detected.

1.3 Synthetic Nonpeptide Oligomer or Small Molecule Libraries

Since the advent of combinatorial peptide libraries, nonpeptide oligomer or small molecule libraries have emerged as an exciting alternative development in the combinatorial library field. This has drawn special attention from the pharmaceutical industry, since ligands isolated from such libraries are often smaller than peptides and may contain lipophilic, aromatic, or heterocyclic structures. Therefore, ligands



# Subunits/coupling step	# Permutations for a trimeric library
20	20^3 = 8 000
50	50^3 = 125 000
100	100^3 = 1 000 000
500	500^3 = 125 000 000

(c)

identified from such combinatorial libraries are more likely to be able to cross cell membranes, making them ideal candidates for drug development. Ideally, the small molecule library should have a molecular weight of 300 to 500 dalton. Usually, this translates to a trimeric library. Fig. 3 illustrates the basic principle of a nonpeptide oligomeric library (Fig. 3a) and a small molecule trimeric library (Fig. 3b). For the small molecule trimeric library, the building blocks can be assembled in three different ways: linear (similar to a peptide), branch, and via a scaffold. For the latter approach, depending on the size, rigidity, and chemical nature of the scaffold, the presentation of the randomized subunits can be vastly different. Fig. 3c shows the number of possible permutations available in a random trimeric library. For example, even with 100 possible subunits per coupling cycle, a trimeric library will yield a million possible permutations. Currently, a few thousand carboxylic acids, primary or secondary amines, alcohols, acid halids, sulfonyl halids, alkyl halids, isocyanates, or aldehydes are commercially available. They are all potential subunits for the generation of small molecule libraries.

Because of the high coupling efficiency of solid-phase peptide synthesis, synthetic peptide libraries were first used in the

synthetic combinatorial library field. For the nonpeptide library synthesis, amide bond formation has been commonly used because of its high efficiency of coupling. Over the past decade, many other reactions have also been successfully applied to the library format, such as urea formation, reductive alkylation, *N*- and *O*-alkylation, Wittig reaction, Mitsunobu reaction, 1,3-dipolar cycloaddition reaction, Diels–Alder reaction, Michael addition, Aldol condensation, Knoevenagel condensation, Stille reaction, Ugi reaction, Suzuki coupling, and Mannich reaction. Undoubtedly, more and more new efficient coupling strategies will continue to be developed for the library format in the future.

2 Techniques

In general, there are five methods of preparing and screening combinatorial libraries: (i) the biological peptide library method (e.g. filamentous phage), (ii) the spatially addressable parallel library method, (iii) the affinity selection method, (iv) combinatorial library methods requiring deconvolution, and (v) the combinatorial library method based on the OBOC concept. Although amino acids are used throughout the following discussion, other nonamino acid moieties can also be similarly used in the nonpeptide oligomer or small molecule libraries. Features of various library methods are compared in Tab. 1.

2.1 Biological Peptide Library Method

Biological peptide libraries include filamentous phage-display peptide libraries, plasmid peptide libraries, polysome peptide libraries, fimbria libraries, yeast-display libraries, bacterial flagella libraries, and other more recently developed *in vitro* selection methods.

The filamentous phage approach was first introduced by Parmley and Smith in 1988. It involves the insertion of a stretch of random deoxyoligonucleotide into the pIII gene of filamentous phage, resulting in the expression of a random oligopeptide at the amino terminus of the viral pIII coat protein. Each phage particle has on one end five copies of these grafted coat proteins. The phages that bind specifically to an acceptor molecule will then be enriched and isolated via several cycles of panning (e.g. binding to acceptor coated petri dish) and amplification. Finally, the amino acid sequence of the grafted peptide is determined by sequencing the pIII gene of the isolated phage. This very powerful method enables the researcher to routinely generate 10^8 to 10^9 different phages. Furthermore, the size of the grafted peptide or protein is not limited by the constraints of synthetic chemistry, as in the case of the synthetic peptide library. In addition, the library can be easily generated by simply growing the microorganisms. Moreover, the biological library method can take advantage of known protein folds (e.g. immunoglobulin fold, zinc-finger fold, or conotoxin fold) by grafting random oligopeptides on such tertiary folds. However, this biologic approach suffers from three major disadvantages:

1. Only the natural L-amino acids (20 eukaryotic amino acids) can be incorporated into these libraries, and incorporation of unnatural amino acids or other organic subunits into these libraries is generally not feasible.
2. Although simple disulfide cyclization is feasible, and longer peptides with

Tab. 1 Combinatorial library methods: A comparison.

Combinatorial library methods		*Size of library*	*Constrained structure*	*Binding assay*	*Solution assay*	*Screening approach*	*Cost/Resource*	*Multiple use*
Biological library[a]	Phage display	10^7–10^9	Simple disulfide or protein fold	Yes	No	Parallel	Inexpensive; library commercially available, and from many research laboratories	Library can be expanded, aliquoted, and stored frozen
Spatially addressable parallel library	Multipin technology	10^4	Yes	Yes	Yes	Parallel	Moderately expensive pin and crowns; commercially available	Pins can be used a few times without obvious lost of activity; solution peptides afford multiple assays
	SPOTs-membrane	10^4	Yes	Yes	No	Parallel	Moderately expensive; spot-synthesis equipment and custom- spot peptide membrane commercially available	Peptide spot membrane generally not recyclable for subsequent use
	NanoKan technology	10^4	Yes	No	Yes	Parallel	Very expensive equipment and supplies commercially available	Solution compounds can be used for multiple assays
	Chemical microarray	$<10^5$	Yes	Yes	No	Parallel	Moderately expensive; peptide chip or compound chip not yet commercially available	Replicates of compound chips can be made; compound chip generally not recyclable for subsequent use

Synthetic library methods requiring deconvolution	Iterative approach Positional scanning (PS-SCL)	10^6–10^8 10^6–10^8	Yes Yes	Yes Yes	Yes Yes	Convergent[b] Convergent	Not very expensive; library not commercially available; can be easily synthesized by experienced synthetic organic chemist	Positional scanning libraries, once made, can be aliquoted and used for multiple assays
OBOC library	On-bead screening Releasable assay	10^6–10^8 10^6–10^8	Yes Yes	Yes No	No Yes	Parallel Parallel	Not very expensive; library not commercially available; can be easily synthesized by experienced synthetic organic chemist	In principle, on-bead screening library can be recycled for subsequent screenings, but generally not done because library is not too expensive to make
Synthetic library method using affinity chromatography selection		10^2–10^5[c]	Yes	Yes	No	Parallel	Not very expensive; library not commercially available; can be easily synthesized by experienced synthetic organic chemist	Possibly

[a]In general, only the 20 eukaryotic L-amino acids are used in the biological libraries; unnatural amino acids or other organic building blocks can be used for synthetic combinatorial libraries.
[b]With the multistep iterative process, usually only one solution motif will be identified.
[c]In rare exception, a larger library may be used with some success.

specific protein folds (such as immunoglobulin folds) may be used, complicated bicyclic, compact scaffolding, branched structures, or molecules with special chemistry of cyclization are impossible.
3. The screening assays of the biological libraries are generally limited to the binding assays (e.g. panning) and some functional assays such as protease substrate determination.

Synthetic peptide libraries, on the other hand, can generally overcome many of the limitations listed.

2.2 Spatially Addressable Parallel Library Method

Sometimes a collection of peptides is synthesized on solid-phase support in a spatially addressable format. The amino acid sequence of each of these peptides is predetermined. The peptide collection is screened, depending on the library method used, either by a direct solid-phase binding assay or by a solution-phase assay. The positive peptide is then located and its chemical structure determined. The major drawback of this method is that only limited number of peptides can be synthesized and therefore the library is very small. There are four reported techniques based on this strategy: multipin technology, SPOT synthesis, NanoKan, and chemical microarray.

2.2.1 Multipin Technology

In the multipin method, pioneered by Geysen et al., the solid-phase support is a polyethylene pin in a 96-well format. The polyethylene pins are first ''functionalized'' with polyacrylic acid or polymethacrylic acid via irradiation. Each pin is inserted into an adapter that fits over a 96-well polypropylene plate with standard microtiter plate footprint. Each well of the microtiter plate then serves as a separate reaction vessel for the amino acid–coupling steps. In the original publication, analysis was performed by enzyme-linked immunosorbent assay (ELISA) with pin-bound peptides, but later modifications permitted peptides to be released by introducing enzymatic or chemically cleavable linkers and analyzed by solution-phase assay. The multipin system is now commercially available from Mimotopes (San Diego, CA) as Pepsets. Peptide loading of each pin has been increased significantly by introducing the so-called ''SynPhase™ Lantern'' or ''SynPhase™ Crown'' to fit into the tip of each pin.

2.2.2 SPOT Synthesis

Frank synthesized peptides onto cellulose membrane or paper (e.g. Whatman 540 paper) by applying the N_α-Fmoc amino acids and reagents directly onto the sheet in the form of a spot. In this SPOT-synthesis technique, different peptides are synthesized at different locations on a single sheet of cellulose paper. The volumes dispensed create a specific SPOT size determining both the scale of reaction and the absolute number of compounds that can be arranged on an area of a membrane. The compounds synthesized can be evaluated using conventional high-throughput screening techniques while still attached to the membrane or in solution following release of compounds from the membrane. SPOT synthesis is amenable to miniaturization and automation. Automatic machines, such as the Auto-SPOT Robot ASP222 (Intavis Inc., Cologne, Germany), for the synthesis of peptide spots are commercially available. Final analysis of the solid-phase bound peptide is usually

performed by an enzyme-linked colorimetric assay, autoradiographic detection of the bound or covalently linked radionuclide, or phosphorylation of protein kinase substrates. Using a larger spot and with releasable linker, the peptides can be released for solution-phase assays.

Cotton (another form of cellulose) and polystyrene-grafted polyethylene film segments have also been used as solid supports. Recently, polymeric membranes, including hydroxy-functionalized PEG acrylate polypropylene membranes and amino-functionalized ester free PEG methacrylamide polypropylene membranes, have been developed. These new membranes are chemically, mechanically, and thermally more stable and can be used for SPOT synthesis.

2.2.3 NanoKan Technique

In 1985, Houghten first reported the ''tea bag'' method for simultaneous multipeptide synthesis. In this method, batches of resin are sealed inside labeled, porous polypropylene packets. In 1995, the use of mini-baskets (e.g. NanoKan) to encapsulate radio-frequency microchips (R_f tagging) and a sample of resin beads for peptide synthesis was reported and became commercially available as IRORI NanoKan™ system (Discovery Partners International Inc, San Diego, CA). Each of these mini-baskets is scanned with an electronic reader prior to or right after each coupling cycle during the ''split-mix'' synthesis (Fig. 2). Therefore, the synthetic history of each compound in each mini-basket is recorded. At the end of the synthesis, resins in each basket contain a single compound. The compounds are cleaved from the beads inside each mini-basket and placed in a 96-well plate to form a spatially addressable compound library. By utilizing the power of the ''split-mix'' strategy, a few thousand to ten thousands individual compounds can be easily generated. The main advantages of this method are (i) it offers considerable synthetic flexibility, as one may use any resin beads in the synthesis, (ii) peptides or small molecule compounds can be produced in sufficient quantities (1–10 μmol) for purification and complete characterization if desired. However, the IRORI system is very expensive. A less-expensive encoding system, called *Encore* (Torviq Inc., Granger, IN), uses ''necklace'' color tags and multicolor reaction vessels to encode the synthetic history. This system also uses the ''split-mix'' synthesis strategy to generate compound libraries with limited number of compounds.

2.2.4 Chemical Microarray

Chemical microarrays, which predate DNA microarrays, are usually prepared by printing protein, peptide, carbohydrates, small molecule, and other biological molecules on a solid surface. In addition to glass slides, cellulose sheets, polymer-based membranes, or other materials have been used. Glass coated with polymers or dendrimers has also been reported. Chemical microarrays enable investigators to rapidly analyze, in parallel, molecular interactions between immobilized molecules and complex biological mixtures. Screening is accomplished by a binding assay with fluorescent-labeled acceptor molecules or by using a functional assay. They have been widely applied in the field of diagnostics and proteomics. For high-density microarrays (e.g. 2000–3000 compounds per cm^2), the radiographic detection method is probably not practical because the resolution of such detection methods is generally low. Solution-phase assays on microarrays is

difficult, but potentially can be developed. The immobilized molecules on chemical microarrays are generally addressable. Therefore, the chemical identity of each immobilized molecule is known. Many chemical methods for immobilizing these molecules onto solid support have been developed. The three general methods to prepare chemical microarrays are physical adsorption, *in situ* synthesis, and chemical ligation.

Physical adsorption Proteins and macromolecules can be readily immobilized onto a polystyrene surface and nitrocellulose or polyvinylidene difluoride (PVDF) membranes through physical adsorption (nonspecific adsorption). This approach has been used in standard ELISA, dot blot, and Western blot for many years. However, immobilization of small molecules, carbohydrates, or short peptides often requires covalent ligation to the solid surface, unless these molecules are first ligated to a macromolecule prior to adsorption onto the solid support.

In situ synthesis In general, there are three methods for *in situ* synthesis of chemical microarrays: (i) SPOT synthesis, (ii) light-directed parallel synthesis with photolithographic masking methods, and (iii) maskless light-directed synthesis using a digital micromirror array. SPOT synthesis, as described above, uses the standard solid-phase peptide synthesis method to generate low-density peptide arrays (e.g. 25 spots/cm^2). The latter two methods use advanced instruments and light-directed *in situ* synthesis to generate very high-density microarray. In 1991, Fodor et al. reported a photolithographic masking process in conjunction with an amino acid–coupling strategy, which uses photolabile protecting groups (e.g. 6-nitroveratryloxycarbonyl) to synthesize a minute quantity of a total of 1024 peptides on a single glass slide. Each peptide occupies an area of 50 μm × 50 μm. Combinatorial masking strategies are used to decrease the required number of photochemical coupling steps. The method was later improved by using a photolithographic masking method to pattern a polymeric photoresist film on the glass surface. In 1999, the development of a maskless array synthesizer to generate *in situ* oligonucleotide microarrays containing more than 76 000 features, each measuring 16 μm^2, was reported. Independently, Gao and coworkers have reported a similar maskless microarray synthesizer to generate oligonucleotide and peptide microarrays using common building blocks with acid labile protection groups. Deprotection of the amino acids is accomplished by the use of light to generate acid, which allows the growth of the oligomers *in situ*.

One major drawback of *in situ* synthesis is that the available chemistries for such synthesis are more limited. In addition, the efficiency of amino acid coupling using this photochemistry is reported to range between 85 and 95%. The synthetic yield and purity of final products would therefore be a major problem for the synthesis of longer peptide libraries (e.g. 10 to 15 mer). In contrast, chemical ligation of presynthesized products by a commercially available automatic arrayer onto the surface through a covalent bond is generally more efficient and less expensive because each compound needs to be synthesized only once and multiple replicates can be produced simply by spotting.

Chemical ligation For most of the peptide and small molecule chemical microarrays,

the compounds are synthesized as stock solutions prior to immobilization. In the past decade, several combinatorial synthesis techniques have been developed for parallel synthesis of peptides or small molecules. These include the Multipin/lantern system, multisyringe system and the 96 deep-well plate system. These methods are labor-intensive but can be facilitated by robotics. An alternative, more efficient approach is to synthesize large number of compounds using macrobeads (up to 0.1 μmol per bead), bead aggregates (1–10 μmol per aggregate, see below), or the IRORI Nanokans (1–10 μmol per nanokan).

Various chemical ligation methods have been developed to immobilize short peptides or small molecules to the solid support via covalent linkage. Schreiber's group linked thiol-containing compounds to maleimide-derivatized glass slides, via Michael addition, to form a microarray of small molecules. They also reported the formation of ether bonds between the chlorinated glass and hydroxy groups of small molecules to prepare microarrays. Recently, they used diazobenzilidene-functionalized glass slides for immobilization of compounds containing acidic protons, such as carboxylic acids, phenols, and sulfonamides. Rogers and coworkers described the use of disulfide bond formation to immobilize oligonucleotides on thiol-derivatized glass surfaces. The mild reaction of an aminooxy group with ketone and aldehyde has been widely used for chemical microarrays. We took advantage of this highly selective chemoselective ligation reaction to attach unprotected peptides covalently onto the glyoxylyl derivatized glass slide via oxime bond or thiazolidine ring formation. Very recently, we reported an efficient method to prepare glyoxylyl-coated glass surface by coupling acrylic acid to the amino glass surface, followed by oxidation with $NaIO_4/OsO_4$ to form a glyoxylyl group. Salisbury et al. reported a similar approach to make chemical microarray by immobilizing aminooxy-derivatized peptides to an aldehyde-modified glass surface. Houseman et al. reported the ligation of carbohydrates to a gold surface via Diels–Alder reaction. Lesaicherre et al. employed a different chemoselective ligation approach to immobilize C-terminal thioester-modified peptides onto an amino modified glass. This microarray was subsequently used for antibody-based fluorescence detection of kinase activity. Soellner et al. employed the Staudineger reaction to ligate the azide-modified peptide to phospinothioester-functionalized glass surface to form an amide bond, while Kohn et al. used this reaction to immobilize small molecule onto a phosphane-decorated glass slide. Kanoh et al. recently reported a ''nonselective'' immobilization method using the chemistry developed for photoaffinity labeling. In this method, they first functionalized the glass surface with a photoreactive group, such as diazirine. A small molecule was then spotted, and the coupling reaction was initiated by UV irradiation.

2.3 Affinity Selection

Affinity column chromatography has been applied successfully for combinatorial oligodeoxynucleotide library methods in which a large collection of oligodeoxynucleotides is allowed to pass through an acceptor-bound column (e.g. thrombin-Sepharose), and the bound oligodeoxynucleotides are eluted and amplified. After a

few more cycles of binding, elution, and enrichment, the structure of the oligonucleotide is finally determined. However, this affinity technique has been applied to a peptide library only with limited success. The reason is that peptides cannot be amplified or cloned. To have enough material for structure determination, the retrieved peptide generally must be pure and in sufficient quantity (at least a picomole, or 6×10^{11} molecules). Nonspecific binding becomes the major problem if a large library of peptides is used. There is no simple method of isolating a single peptide for sequencing. Despite its limitation, Zuckermann et al. were able to apply the affinity selection method to retrieve an antibody-specific binding peptide from a mixture of peptides in solution. Cantley et al. reported the successful application of the affinity selection method to identify peptide motifs for SH_2 domains and kinase domains of protein tyrosine kinases. Concurrent microsequencing of the retrieved peptide mixture was performed rather than sequencing individual peptides. Therefore, the data could be difficult to interpret and inconclusive, particularly in the presence of more than one motif. In general, because of high background from nonspecific binding, the affinity selection method, with rare exceptions, can be applied only to a relatively small peptide library (e.g. $<$10 000 peptides).

2.4 Library Methods Requiring Deconvolution

In this method, mixtures of peptides are first synthesized and then subjected to biological testing. On the basis of the test results, one may be able to deduce the chemical structure of the active ligand without need of further structure elucidation. However, in general, additional synthesis and testing are needed to reach a final solution. Examples of this library approach are the iterative approach, the positional scanning approach, the orthogonal partition approach, the recursive deconvolution approach, and the recently developed dual recursive deconvolution.

Fig. 4 shows how the amino acid at each position of the ligand can be defined by an iterative process that involves multistep synthesis and analysis. For example, in a combinatorial hexapeptide library, one of the 20 amino acids is incorporated into positions 1 and 2, while all 20 amino acids are incorporated (presumably in an equimolar ratio) into the remaining four residues. This results in the generation of 400 (or 20×20) peptide mixtures (step 1, Fig. 4). Each mixture contains 160 000 (or 20^4) different peptides. Each of these 400 peptide mixtures is then subjected to screening, from which the ''active'' amino acids for the first two positions can be defined. In step 2, the first two ''active'' residues are fixed, and one of the 20 amino acids is incorporated into position 3, while all 20 amino acids are incorporated into the remaining three residues. This results in the generation of 20 peptide mixtures. Each of these 20 mixtures is again screened, and the third set of ''active'' residues is then defined. The same iterative process is repeated for three more cycles until the last residue has been defined.

A synthetic combinatorial library constructed and screened by means of an iterative approach was first described by Geysen in the multipin system, where a peptide mimotope was defined for a monoclonal antibody. The pin-bound peptide library was screened by means of ELISA. Subsequently, Houghten et al. described a similar method termed as synthetic peptide combinatorial libraries (SPCLs), but the peptides were released into solution

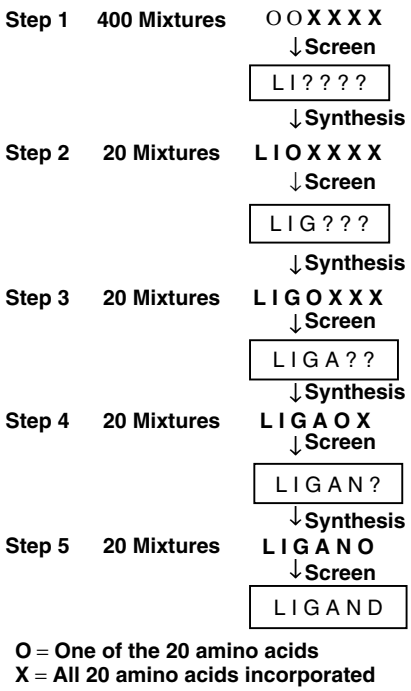

Fig. 4 Scheme of the iterative approach for combinatorial library method that requires deconvolution.

prior to screening. The libraries are prepared using 4-methylbenzhydrylamnine (MBHA) polystyrene resin and standard *t*-Boc/Bn chemistry. To ensure equimolar random mixtures, a ''split-mix synthesis'' method (see Fig. 2) is used. The peptide mixtures are deprotected and cleaved from the resin with the low/high hydrogen fluoride method. Peptide mixtures are then extracted with water or dilute acetic acid and lyophilized. The major advantages of the SPCL approach are that a large number (10^6–10^8) of peptides can be synthesized and screened. Also, many existing biological assays, including functional assays, can be adapted to this screening process (because it is a solution-phase assay). One concern is that not all the peptides in the library are extractable by water or dilute acetic acid.

Subsequently, Houghten et al. described the ''positional scanning methodology'' in which 20 mixtures of hexapeptides were synthesized with one of the 20 amino acids incorporated into one residue, while all 20 amino acids were incorporated into the rest of the five positions. By scanning these 120 mixtures, it is possible to define each active residue. However, this approach will work well for acceptor molecules for which no more than one motif is possible. If an acceptor has multiple motifs, the results will likely be scrambled and sometimes uninterpretable.

Houghten et al. also described a so-called ''libraries from libraries method,'' in which the random peptide libraries are chemically modified, while the protected peptides were still attached to the solid phase. Examples of such chemical transformation are permethylation, perbenzylation, perallylation, and decarbonylation. The modified libraries are then released for solution-phase testing.

Deprez et al. introduced the orthogonal partition approach of deconvolution by synthesizing and screening multiple orthogonal sub-libraries. Erb et al. reported a recursive deconvolution strategy. In this approach, a ''split-mix synthesis'' method is used to generate the combinational library. During each step of synthesis, a portion of the resin from each reaction vial is set aside and catalogued. These set-aside resins are then used to generate sub-libraries at each iterative step in a more efficient manner.

Dual recursive deconvolution (DRED) was introduced by Fenniri et al. as a hybrid approach of deconvolution. In this method, a new (encoding) dimension was added to the classical deconvolution strategies. DRED operates through the

iterative identification of the first and last randomized positions of active members. The last position of the combinatorial library can be readily obtained from pool screening after the last step of the split-mix synthesis, while the first position need to be encoded by the unique vibrational fingerprint of the resin beads used. Once the first and last positions are identified, the remaining positions are subjected to the same deconvolution process.

2.5 OBOC Library Method

We first reported the OBOC concept in 1991. The peptide is synthesized on solid-phase beads using a ''split-mix synthesis'' method (Fig. 2). Since each bead is in contact with only one amino acid at a time during each coupling cycle and the reaction is driven to completion, each bead expresses a single peptide entity (Fig. 2). The peptide library, consisting of millions of beads, each with a unique peptide, is then subjected to mass screening. The reactive beads are identified and physically isolated, and each is subjected to microsequencing with Edman degradation chemistry. Each 80 to 100 μm bead contains approximately 100 pmol of peptide (6×10^{13} molecules) and is more than enough for microsequencing. If there is a predominant common motif, instead of sequencing individual bead, 10 to 50 ''active'' beads can be pooled for concurrent microsequencing. The methods of screening include both on-bead binding assays and solution-phase biological assays.

TentaGel resin (Rapp Polymere, Tubingen, Germany) is a good choice for OBOC peptide libraries because of its uniformity in size as well as its nonstickiness. It consists of hydroxyethyl-polystyrene beads onto which have been grafted 3000 to 4000 dalton PEG linkers. A functional group, for example, hydroxyl or amino, is located at the end of the linkers. This resin can be swollen in a wide range of solvents from water to toluene. The PEG linker is advantageous for many biological assays. For protease substrate screening, porous beads such as PEGA [bis(2-acrylamidoprop-1-yl) poly(ethylene glycol) cross-linked dimethyl acrylamide and mono-2-acrylamidoprop-1-yl [2-aminoprop-1-yl] poly(ethylene glycol)] beads (Calbiochem-Novabiochem, San Diego) are preferable.

For the on-bead binding assays, standard enzyme-linked colorimetric assays, fluorescent assays, or radionuclide assays can be used. The enzyme-linked colorimetric assay is the simplest because it adapts the standard Western blot technology and no special equipment is required. Fluorescent microscopy has been used successfully to screen bead libraries with fluorescent probes. However, the greatest potential using a fluorescent assay to analyze a library is to use a fluorescent-activated bead sorter (COPAS™ BIOBEAD, Union Biometrica, Inc, Somerville, MA). In a standard analysis, 30 000 beads can be sorted per hour.

The ''on-bead'' binding assay was modified to identify protein kinase substrate motifs by covalently modifying the peptide bead with [γ-^{32}P] ATP and a protein kinase. The phosphorylated peptide-bead library is washed thoroughly and immobilized on a glass plate with agar. The ^{32}P-labeled beads are then detected by autoradiography, and individual radiolabeled (''active'') beads are isolated for microsequencing. Another screening approach is to use a color probe to screen a library, to take advantage of the ease with which positive beads may be identified by the color change. For example, we have identified small peptides that bind specifically to an indigo dye.

The OBOC library method has been successfully applied to identification of protease substrates and inhibitors. Highly porous PEGA resin was used for the peptide library construction because it allowed the enzyme to gain access to the bead interior. For protease substrate determination, OBOC peptide libraries with fluorescent dye incorporated at the C terminus and a quencher at the N terminus have been used. Peptide beads susceptible to protease cleavage will fluoresce. These fluorescent-labeled beads were isolated under a fluorescent microscope, or isolated by a fluorescent-activated bead sorter and subjected to microsequencing. This method is a powerful tool to investigate the protease activity and specificity since it gives information about the substrate sequence, the cleavage point, and the degree of cleavage. Meldal et al. reported a so-called ''one-bead two-compounds'' approach to directly identify protease inhibitors. This approach combines the OBOC concept and fluorogenic quench screening strategy. In this method, each bead contains a putative protease inhibitor along with a fluorescence-quenched substrate for the protease. Kodadek et al. recently reported the use of fluorescent-labeled proteins as probe to screen OBOC peptoid (*N*-substituted oligoglycine) libraries. In order to increase the signal-to-noise ratio, they later reported the use of quantum dots, rather than organic fluorescent dye, as a fluorophor to label the target protein.

The OBOC method has also been applied to the identification of cell surface binding ligands, using a whole-cell binding assay. In this assay, peptide-bead library is mixed with intact cells, and beads coated with a monolayer of cells are isolated for microsequencing.

To minimize nonspecific binding, blocking agents (e.g. bovine serum albumin or gelatin), salt (e.g. 0.26 M NaCl), and nonionic detergent (e.g. Tween-20) are routinely added to the screening buffer. Furthermore, with a dual color detection scheme in the presence or absence of a competing ligand, most of the false positive beads can be eliminated, thus increasing the efficiency of microsequencing, which is the rate-limiting step of the process.

Besides binding assays, the OBOC method has been adapted to solution-phase assays. Peptide bead libraries with dual orthogonal cleavable linkers are used, and peptides can be released sequentially with a two-step process into solution for biological testing. Conditions for the release of peptides from the resin beads are mild and nondenaturing. They involve neutralization in step 1, and alkali treatment followed by neutralization in step 2. In this two-step process, approximately 500 peptide beads are aliquoted into each well of a microtiter filtration plate (96-well format). Upon neutralization, the peptides are released from the first linker into solution for solution-phase assays (step 1). Peptide beads from the positive wells are then redistributed at the much lower density of one bead per well. Upon alkali treatment, peptides are released from the second linker. After neutralization, the released peptides are subjected to solution-phase assays. Thus, similar to the solution-phase combinatorial library approach described by Houghten, the screening can be adapted to many existing biological assays. Positives can be tracked to the originating bead, allowing the residual peptide on the bead to be analyzed by a microsequencer. Depending on the size and loading of each bead, 1 to 10 μM compound (in 100 μL assay volume) can be released for standard solution-phase biological assays. However, this approach suffers some disadvantages,

for example, it is not easy to retrieve minute amounts of soluble compounds (100 pmol) from one single 80 to 100 μm bead, and often there is not enough material from one single bead for biological assays. Schreiber et al. reported the use of macrobeads (500 μm) to develop releasable OBOC libraries in microtiter plates. However, the capacity of these macrobeads is still rather limited (<0.1 μmol/bead). Further increases in size of the bead lead to incomplete coupling because reagent diffusion will become a limiting factor. We have recently developed a ''one-aggregate one-compound'' method to address this problem. Bead aggregates were prepared by cross-linking the TentaGel resin beads with glutaraldehyde. Each bead aggregate contains some color beads with an orthogonal protecting group that can be chemically encoded during the library synthesis and retrieved for decoding after biological screening. The loading capacity of each bead aggregate ranges between 1 and 10 μmol, for example, 10 to 100-fold more than that of the macrobeads used by Schreiber's group. By exploiting the OBOC concept, this ''one-aggregate one-compound'' method is highly efficient and much more economical than the IRORI Nanokan® system. Such diverse solution-phase libraries can be either screened with the standard solution-phase assay or used to print multiple replicates of chemical microarrays (see Sect. 2.2.4).

A more elegant and potentially much more powerful approach to screen the OBOC libraries is the *in situ* solution-phase releasable assay, in which the compound-bead libraries are immobilized in a thin layer of agar. Compounds from each bead are then released to the vicinity of each bead for solution-phase assay in the semisolid. This method works particularly well for identifying antimicrobial and anticancer agents, since a zone of growth inhibition around the positive beads can easily be detected. We have used this *in situ* releasable assay to identify anticancer agents. The compound beads were immobilized in a thin layer of soft agar together with cancer cells. After being cleaved from the linker, compounds from each bead were released and diffused outward. A clear zone of growth inhibition around the positive bead was detected by adding 3-(4,5-dimethylthazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) to the culture plate, in which only the live cells were stained purple. Jayawickreme et al. reported a ''cell-based lawn format'' utilizing an *in situ* photocleavage method to release the compound. These *in situ* releasable solution-phase assays have great potential but will require further development before they can be reliably used for drug screening. For example, special solid supports need to be developed such that all compounds will diffuse freely out of all beads into the surrounding media.

The main advantages of the OBOC method are that a large number (10^6–10^8) of compounds can be synthesized and screened rapidly, and either one or a combination of both on-bead binding and solution-phase assays can be used. In addition, since it is a single-step process that does not require deconvolution, multiple peptide ligands with completely different motifs can often be identified in a single screen. That is, the OBOC method is a parallel approach. This is the opposite of the (convergent) iterative approach, where multistep synthesis and screening results in the emergence of only one, but not necessarily the best, solution motif.

Since the compound beads in an OBOC combinatorial library are spatially separable, an OBOC library can be considered

as a huge chemical microarray that is not addressable. Many of the detection methods developed for OBOC combinatorial libraries have also been used to screen chemical microarrays. These include colorimetric assays, fluorescent assays, radioactive assays, and whole-cell binding assays. Other assays that do not require protein labeling, such as surface plasmon resonance, have also been developed.

Positive compound beads from screening of OBOC library are physically isolated under the microscope. For peptide libraries that are comprised of eukaryotic amino acids, an automatic protein sequencer (e.g. Procise 494, Perkin-Elmer/Applied Biosystems) is routinely used via Edman chemistry to determine the amino acid sequence of the positive beads. The incorporation of unnatural amino acids into peptide libraries not only greatly increases the diversity of the library but also renders some of the peptide library members more resistant to proteolysis. We recently developed methods to sequence peptides containing many unnatural α-amino acids. However, Edman sequencing is time consuming and expensive, compared to mass spectrometry analysis. Youngquist et al. described a ''ladder sequencing'' method by using limited capping after each cycle of coupling followed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) to determine the full peptide sequence of single beads. Later, this method was modified with either replacement of the capping step, by the partial incorporation of a methionine residue at each coupling stage, or by the use of the dual capping groups and analysis of molecular ion redundancy to directly elucidate the structure by mass spectrometry analysis. Very recently, Pastor et al. have further improved this method by using an isotope-labeling strategy to terminate the N terminus and analyzing the generated ladders with ion-extraction mass spectrometry.

2.6 Nonpeptide Oligomer or Small Molecule Libraries

Within two years from the initial publications by Lam and Houghten on screening large synthetic peptide libraries in 1991, several groups reported on the application of similar approaches for the synthesis and screening of nonpeptide oligomeric libraries. The three general strategies for subunit assembly to form linear, cyclic, and branched oligomeric libraries are shown in Fig. 3a. In the case of the linear strategy with repeating subunits, the Chiron group described the ''peptoid'' approach with N-substituted glycines as subunits. Subsequently, they modified their synthetic method by using α-haloacetic acid submonomers and a variety of primary amines as subbuilding blocks.

Cho et al. described the oligocarbamate libraries using N-protected amino carbonates as the monomers. Because of the repetitive nature of the synthetic process, similar to the peptide library, both the peptoid and oligocarbamate strategies allow the synthesis of a longer linear oligomer. However, as indicated earlier, the main advantage of the nonpeptide library method is that it allows the synthesis and screening of a library of relatively rigid small molecules. These small molecules (e.g. trimeric structures with molecular weight of 300–500) are ideal candidates for drug development because they have improved physical properties for crossing the biological membranes. The subunit assembly strategies for such a library could

involve linear, branch, or scaffold linkage methods.

The scaffolding approaches of presenting several pharmacophores into space have been described by many groups, but Ellman and coworkers were the first to publish on the scaffolding approach in a library format. They described the assembly of a small molecule, 1,4-benzodiazepine derivative library with high yield. Since then, there have been numerous reports on the synthesis of different rigid small molecule libraries. Several thousands of nonpeptide libraries have been reported. These include hydantoin, benzopyran, tetrahydrofuran, acylpiperidine, β-turn mimetics, arylacetic acid, prostaglandin, purine, triazine, quinazoline, phenylamine-pyrimidine, phthalazine, and steroid libraries. Various chemical reactions have also been successfully applied to the synthesis of libraries, including C–C formation reaction. Undoubtedly, many more examples of applications of small molecule libraries will be published in the next few years.

2.7 Encoding and Decoding for Nonpeptide Libraries

If combinatorial nonpeptide or small molecule libraries that require deconvolution are used, structure determination with physicochemical methods is not needed because the structure is deduced from the synthetic algorithm. However, in the OBOC approach, one needs to isolate the individual ''active'' bead and determine the chemical structure either directly or via an encoding strategy. Since nonpeptide structures are not amenable to structure determination with Edman degradation, alternative strategies have been developed. Several research groups have developed various physical and chemical encoding methods to encode OBOC nonpeptide libraries. Chemical encoding is ideal for OBOC nonpeptide libraries since it can encode large libraries, for example, >10 000 members. Three encoding principles are illustrated in Fig. 5. Chemical tags are added to the bead during the synthetic steps so that the synthetic history of each compound bead in the chemical library can be recorded. These chemical codes can then be decoded by spectroscopic or chromatographic methods such as HPLC (high performance liquid chromatography), GC (gas chromatography), MS (mass spectrometry), fluorescence, IR (infrared), NMR (nuclear magnetic resonance) spectroscopy and electron capture. Several chemical encoding methods have been reported, including using oligonucleotide tags, peptide tags, fluorophenyl ether tags, secondary amine tags, and trityl-based mass tags. A separating anchor with differential protecting groups (Fig. 5a) or a growing chain utilizing separate branches (Fig. 5b) on the solid phase are used for the library synthesis. One protecting group is used for the synthesis of the testing ligand and the other for the coding sequence. For every cycle of the split-mix synthesis, coding subunits are coupled immediately after coupling ligand subunits but before the mixing of the resins. At the end of the library synthesis, each bead has a testing ligand and a corresponding coding sequence. The chemical structure of the isolated ligand is then determined by analyzing the structure of the coding sequence. With this sequential coding approach, the peptide tag can be determined by means of Edman degradation, and the oligonucleotide tag can be determined by polymerase chain reaction followed by DNA sequencing. One-step digital or binary coding systems have been developed.

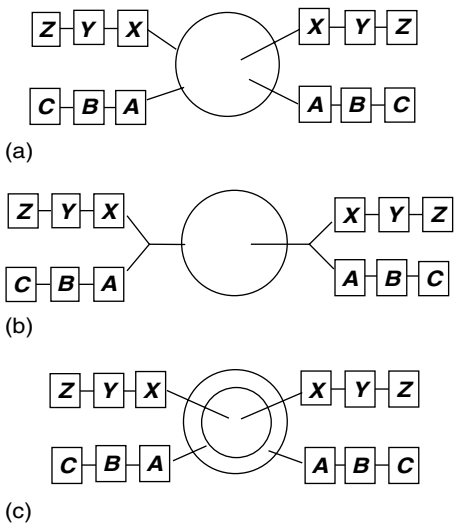

Fig. 5 Principle of encoding for nonpeptide combinatorial library. (a) Sequential coding; (b) Branch coding; (c) Spatial separation of testing and coding molecules. *A*, *B*, and *C* are building blocks; *X*, *Y*, and *Z* are coding tags; *X* encodes *A*, *Y* encodes *B*, and *Z* encodes *C*.

These use specially modified amino acids (analyzed by HPLC) or halophenol derivatives (analyzed by electron capture gas chromatography) that elute at different regions of the chromatogram. The elution range signifies the coding position (residue 1, 2, or 3, etc.), and the binary combination of position with specific peak in the range signifies the subunit used in that position. These methods have already been successfully applied to the synthesis and screening of nonpeptide libraries.

However, these methods have two major limitations: (i) the coding tags may negatively affect the binding of the ligand structure to the target acceptor molecule, and (ii) these chemical encoding methods require that the chemistry of adding the tag and synthesizing the library be orthogonal, resulting in nearly doubling the number of synthetic steps. To solve the problem of interference by the coding tag, we have developed a novel and robust peptide-based encoding strategy. In this method, the testing molecule presents on the bead surface, and the coding tag resides in the interior of the beads (Fig. 5c). This encoding method is highly efficient, as each of the building blocks is incorporated into the testing arm (bead surface) and the coding peptide backbone (bead interior) simultaneously (Fig. 6). This eliminates many extra synthetic steps of standard chemical encoding. The positive beads identified through screening can be isolated, and the peptide coding tags, which consist of α-amino acids with side chains derivatized by the building blocks, can be readily decoded by Edman microsequencing. We have successfully applied this encoding method to a number of peptidomimetic and small molecule libraries. This peptide-encoding method, however, is relatively slow because Edman chemistry for microsequencing is slow. Recently, we have further improved our encoding method by incorporating triple or quadruple cleavable coding arms in the bead interior so that the coding tag can be decoded with MS (Fig. 7). Prior to library synthesis, the inner core of each bead is derivatized with three or four different coding arms on a cleavable linker. Similar to the above-mentioned peptide-based encoding method, each of

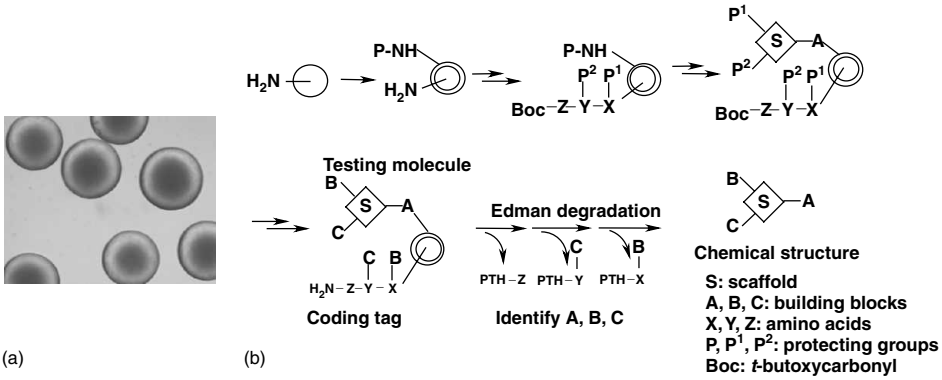

Fig. 6 (a) Photomicrograph of the topographically segregated bifunctional bead. Free amines at the inner core of each bead stained blue because they reacted with bromophenol blue. (b) General encoding and decoding scheme of peptide-encoded small molecule library (see color plate p. xxiii).

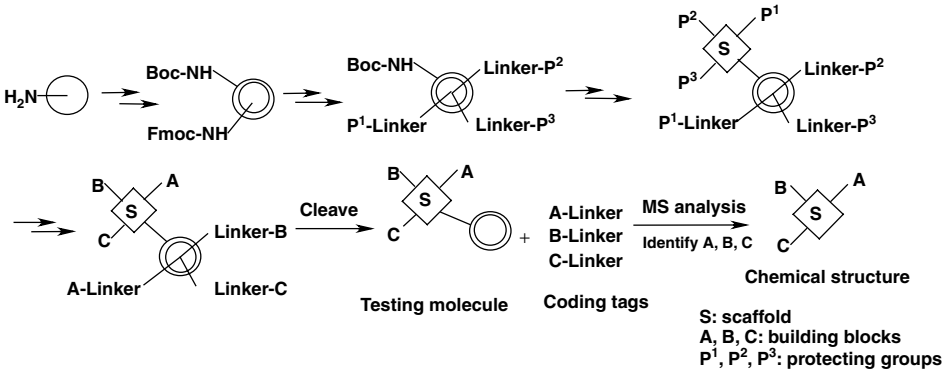

Fig. 7 General encoding and decoding strategy of the MS-encoded small molecule library.

these coding arms contains a functional group that is identical or related to the functional groups on the scaffold of the testing compound to be synthesized. Also, each building block will react with the testing and encoding arms simultaneously. Consequently, no extra synthetic steps for encoding are needed. After screening, the coding tags in the positive beads are released, followed by molecular mass determination using matrix-assisted laser desorption/ionization-Fourier transform mass spectrometry (MALDI-FTMS).

Very recently, we combined the bilayer bead concept with the ''ladder-synthesis'' method (see above), which has been used successfully in sequencing active beads isolated from small molecule libraries. In this method, the small molecule library is synthesized such that library compound is confined to the outer layer of the bead and its ladder fragment resides in the bead interior. Releasates of these compounds and ladder fragments from the positive bead are analyzed by matrix-assisted laser desorption/ionization mass

spectrometry (MALDI-MS)). On the basis of the mass difference between the library compound and its ladder fragments, the identity of each building block can be determined.

3 Application

Over the last decade, the synthetic combinatorial library approach has been applied successfully to various biologic systems. These include identification of ligands for antibodies (both continuous and discontinuous epitopes), streptavidin, avidin, opioid receptors, melanin-stimulating hormone (MSH) receptor, surface idiotype of B-cell lymphoma cell lines, bombesin receptor, molecules A2 and B7 of major histocompatibility complex (MHC) class I cytokine receptors, signal transduction adaptor molecules such as SH_2 and SH_3 domains, adhesion molecules such as gpllb/Illa, specific metal ions, double-stranded DNA, and organic dye molecules. In addition, peptides with antiprotease (including HIV protease), antiinflammatory, antibacterial, and catalytic activities have been discovered. Furthermore, substrate motifs for various protein kinases, proteases, or other post-translational modification enzymes have been elucidated. Peptide-based enzyme mimics (artificial enzymes) have been identified through screening combinatorial peptide libraries. We reported the use of a ^{32}P or ^{33}P phosphorylation assay and an autoradiographic method to identify specific and efficient peptide substrates for protein kinases. We have also described the use of a whole-cell binding assay in which bead libraries are mixed with live cells, to identify cell surface binding peptide ligands specific for prostate cancer, nonsmall cell lung cancer, and lymphoma cells. Tab. 2 summarizes some of the published applications of combinatorial library methods.

Combinatorial chemistry has also successfully applied to the field of material science. This includes the discovery of polymeric structures with specific physical, chemical, electrochemical, photochemical, or photoelectric properties.

Tab. 2 Biological applications of combinatorial library methods.

Methods	*Application examples*
Biological libraries	MHC class II molecule binding peptides Peptide substrate for tissue plasminogen activator Peptide substrates for HIV-1 protease Epitope mapping for B-cells Cell surface ligands Binding to the vasculature of various organs and tumors by injecting the phage library intravenously into live animals
Spatially addressable parallel library	Epitope mapping for monoclonal and polyclonal antibodies T-cell epitopes MHC class I molecule binding peptides

Tab. 2 (*continued*)

Methods	*Application examples*
	Structure-activity relationship of substance P
	Protein kinase substrates and inhibitors
Synthetic library methods requiring deconvolution	Mimotopes/epitopes for monoclonal or polyclonal antibodies
	T-cell epitopes
	Protease inhibitors
	Antibacterial agents
	Opioid receptor ligands
	Molecules with catalytic activity
	Molecules with hemolytic activity
	α-Adrenergic receptor ligand (from peptoid libraries)
	CAMP-dependent protein kinase motif
	DNA-binding peptides
	Tab-2-binding peptides
One-bead one-compound library method	Mimotopes/epitopes for monoclonal antibodies
	MHC class I binding motif
	SH_3 domain-binding peptides
	SH_2 domain-binding peptides
	GpIIb/IIIa-binding motif
	Melanin-stimulating hormone-receptor ligands
	Bombesin-receptor ligands
	Streptavidin
	Avidin
	Factor Xa inhibitor
	Protease substrates and inhibitors
	Antibacterial agent
	CAMP-dependent protein kinase motif
	$P60^{c-src}$ protein kinase motif
	Small organic dye-binding peptides
	Artificial receptors
	Anti-insulin monoclonal antibody recognizing a discontinuous epitope
	Surface idiotype of B-cell lymphoma cell lines
	Ligands for an anti-β-endorphin antibody
	Ligands for cell surface receptor of live cells
	Peptides with catalytic activity
Synthetic library method using affinity chromatography selection	Epitope mapping for monoclonal antibodies
	Protein kinase substrates and inhibitors
	SH_2 domain-binding peptides
	Kinase domains of protein tyrosine kinases

Note: Biological libraries are limited to peptide libraries with eukaryotic amino acids. The remaining four methods can be applied to peptide or nonpeptide libraries.

Screening of diverse random compound libraries for specific biological or physical properties often leads to the discovery of lead compounds that have low potency. On the basis of the structural motif of these primary leads or lead compounds determined by other means, secondary or focused libraries may be designed and screened under higher stringency. Compounds identified from such secondary screen often exhibit higher potency. This approach can be repeated several times to further optimize the compound. Although combinatorial chemistry can be applied to biological systems without any known structural data such as X-ray crystal structural of target proteins, structural data do help. For example, one may apply molecular modeling techniques to select appropriate scaffoldings and building blocks so that combinatorial libraries with better ''hit rates'' can be designed. The development of these combinatorial library methods not only facilitates the drug discovery process but also provides important information for the understanding of molecular recognition.

4 Perspectives

Tab. 1 compares five peptide library methods. In general, there are only four methods of generating and screening libraries of 10^6 to 10^8 peptides: biological peptide library, combinatorial library requiring deconvolution, the OBOC library, and the affinity selection method. The spatially addressable parallel library method, while very useful, can only generate limited number of compounds (e.g. less than 10 000). Each method has its advantages and disadvantages, and in every case the choice of methods will depend on the specific application and the resources and expertise available. Sometimes, it may be advantageous to combine some of these methods together. Because of the versatility of synthetic chemistry, enormous research efforts have been given to the development of totally nonpeptide small molecule libraries. New methods for library synthesis, via solid-phase synthesis methods or solution-phase synthesis methods, will continue to be developed. Microwave-assisted reactions will continue to be developed to improve the coupling yields. Novel building blocks and multifunctional scaffoldings will be developed and commercialized. Novel encoding methods for OBOC combinatorial libraries will continue to evolve. New solid supports with various composition, shape, and form will be developed for various combinatorial chemistry applications. As an alternative to synthetic chemistry, enzyme-catalyzed solid-phase biosynthetic methods may also be used. In fact, these biosynthetic methods show great potential in the generation of oligosaccharide or polyketide libraries whose chemical synthesis may otherwise be difficult.

The combinatorial library method represents a powerful technique for basic research and drug discovery. It has also proven to be extremely useful in material and catalyst development. Chemical microarray is a unique form of combinatorial library that is currently being exploited in the field of drug discovery, proteomics, and the development of novel diagnostics. In the next few years, highly sensitive analytical techniques will be developed to quantitate the binding of target proteins to such chemical microarrays and to determine the identity of the bound proteins to such chemical microarrays. We anticipate that combinatorial chemistry will continue

to have a major impact on the field of drug development and chemical biology in the years to come.

Keywords

Apoptosis
The process of programmed cell death; the body's normal method of disposing of damaged, unwanted, or unneeded cells.

Cytoskeleton
An internal network of filaments and tubules that give the eukaryotic cell its ability to move, to assume a characteristic shape, to divide, to arrange its organelles, and to transport them from one location to another.

Endocytosis
The process by which soluble material is internalized into a cell via invagination of cell surface membrane.

Endosome
A membrane-bound organelle that carries material newly ingested by endocytosis. It passes many of the materials to the terminal degradative compartment (lysosome) for degradation.

Lysosome
A membrane-bound organelle containing digestive enzymes with acidic pH optima. Lysosomes are found in almost nucleated all cells and are vehicles for secretion as well as digestion.

Opsonin
A substance naturally present in the blood that renders bacteria susceptible to phagocytosis through the promotion or enhancement of attachment via a cell surface receptor.

Phagocyte
An immune cell that engulfs and digests dead or dying cells, microorganisms, or other foreign bodies in the bloodstream and tissues.

Phagosome
A vacuole formed by the internalization of surface membrane along with an attached particle.

Pseudopod
Literally ''false foot''; extensions of the plasma membrane used for a variety of cell activities, most notably locomotion and phagocytosis.

Phagocytosis, the process by which eukaryotic cells internalize other cells, cell fragments, protein aggregates, and foreign bodies, has an essential role in physiology. In primitive organisms, it is primarily used for acquisition of nutrients, whereas, in higher organisms, it occurs in specialized cells such as monocytes and neutrophils and is required for a wide variety of biological events. These include clearance of infectious agents and senescent cells, and tissue repair and remodeling. Because phagocytosis is essential for survival and homeostasis, complex signaling pathways have evolved both to regulate the engulfment process and to couple uptake of particulate material with appropriate cellular responses. Many pathogens manipulate the signaling pathways involved in phagocytosis to avoid phagocytic killing and to establish intracellular infections within phagocytes.

1 Phagocytosis and Physiology

Phagocytosis is the process by which eukaryotic cells internalize other cells, cell fragments, protein aggregates, and foreign bodies. While targets for engulfment may be up to many microns in diameter, the term *phagocytosis* is generally reserved for particles that are more than 1 μm in diameter, because, at this size, the mechanisms for internalization clearly differ from those used for endocytosis of soluble material. Phagocytosis was first described in 1883 by Elie Metchnikoff, who observed cells in starfish larvae capable of ingesting and destroying foreign substances. His work led to the discovery of the role of phagocytes in host defense against pathogens. This was a significant contribution to the field of immunology. Since that time, studies of phagocytosis have not only elucidated aspects of immune defense but also cell biology, developmental biology, microbiology, and ecology.

Phagocytosis is a component of many different physiological processes. For example, amoebae phagocytose bacteria and other organisms as a food source, and the nitrogen released by soil amoebae stimulates the growth of nearby plant life. In higher organisms, the most prominent roles for phagocytosis include the removal of tissue debris after injury, senescent erythrocytes, apoptotic cells, and the destruction and removal of invading microbes.

Survival of protozoan amoebae depends on their ability to internalize particulate matter. These single-celled animals feed primarily on bacteria, soluble organic matter, and sometimes fungi. Soil protozoa play an important role in mineralizing nutrients, making them available for use by plants and other soil organisms. After soil protozoa internalize and digest bacteria, they release excess nitrogen, and since they are concentrated near plant roots, the plant can benefit from this supply of nutrients. These plants, in turn, are used as a food source for many vertebrates. In

this way, phagocytosis performed by tiny, single-celled organisms is a vital part of the food chain.

Marine bivalves, such as mussels, oysters, and clams, utilize phagocytosis as a primary means of defense against microbes. Bivalves filter great volumes of water through their gills. These invertebrates trap and accumulate large numbers of microorganisms present in the water. To cope with this challenge, bivalves possess phagocytic cells called *hemocytes*, which engulf and destroy pathogenic microbes.

In mammals, phagocytosis is the primary mechanism for removal of invading microorganisms, dead and dying cells, tissue debris, protein aggregates, and foreign bodies. Phagocytosis is essential for host defense against infectious diseases, for organ remodeling in embryonic development, for tissue repair after injury, and for the removal of aging and senescent cells. Although many mammalian cells are able to perform phagocytosis, it is the primary function of specialized leukocytes, monocytes, and neutrophils. These phagocytes circulate throughout the body in search of microbes and senescent cells. Once internalized, a number of signaling pathways are initiated within phagocytes, which regulate complex host immune responses such as inflammation.

2 Types of Phagocytes

2.1 Professional Phagocytes

The host defense aspects of phagocytosis require recognition of potential pathogens. This is a function of specialized leukocytes, myeloid cells called *macrophages*, *polymorphonuclear leukocytes* (PMNs), and *dendritic cells*, collectively referred to as *professional phagocytes*. All professional phagocytes originate from precursor cells in the bone marrow. They migrate through blood and tissues, surveying for bacteria, foreign particles, and cellular debris, which they internalize and digest. Although PMNs, macrophages, and dendritic cells share the common function of phagocytosis, each cell type has distinct functions in the immune system.

2.1.1 Macrophages

Mononuclear phagocytes are released from the bone marrow as monocytes, which migrate from the bloodstream into different tissues, where they further differentiate into mature macrophages. The phenotype of these cells is highly dependent on the tissue in which they reside. Kupffer cells, resident macrophages of the liver, remove dying erythrocytes and other debris from the bloodstream. Alveolar macrophages in the lung ingest and remove inhaled particles that are small enough to reach the terminal airways. Microglia in the central nervous system ingest degenerated myelin. Macrophages are also found in the submucosa of the gastrointestinal and urogenital tracts, in the skin, and in the synovial membranes lining joint cavities. At these sites, they remove bacteria that frequently cross epithelial barriers into these tissues from the gastrointestinal tract or the lung.

Macrophages have important roles in the innate immune response. They internalize and destroy infectious agents, and release inflammatory mediators, including interleukin (IL)-8, which attracts neutrophils to sites of infection, and IL-12 or IL-4, which activates T cells. In response to IL-12, T cells produce interferon gamma, which augments the effector functions of macrophages.

2.1.2 Polymorphonuclear Leukocytes

Polymorphonuclear leukocytes (PMNs), or neutrophils, are short-lived cells (average life span is 24 to 48 h) equipped with numerous antimicrobial effector mechanisms. Unlike resident macrophages and immature dendritic cells, PMNs do not reside in peripheral tissues prior to infection. Rather, PMNs are recruited from the circulation to sites of infection by signals produced by pathogens and other immune cells. This process of oriented migration in response to chemical gradients is called *chemotaxis*. Recruited PMNs accumulate at sites of infection, phagocytose pathogens and kill them, using several microbicidal mechanisms. PMNs contain several types of granules that are specialized for the storage and secretion of antimicrobial products, including lysozyme, which can digest the peptidoglycan component of most bacterial cell walls, and myeloperoxidase, which converts hydrogen peroxide and hydrochloric acid to hydrochlorous acid. After PMNs internalize a pathogen, the membrane-bound granules fuse with the phagosome, placing the effector molecules in direct contact with the ingested material. In addition to intracellular killing of phagocytosed bacteria, PMNs are also capable of killing extracellular microbes by secreting granules into the extracellular space.

2.1.3 Dendritic Cells

Dendritic cells (DCs) are so named because of the branched morphology of their surface. DCs may develop directly from common myeloid progenitors or from monocytes and plasmacytoid cells. The different progenitors give rise to different subsets of DCs: Langerhans DC, interstitial DC, monocyte-derived DC, and plasmacytoid-derived DC. DCs are found in virtually all organs.

DCs are best known for their role in the initiation of adaptive immune responses. Their function in immunity alters with their maturity. Immature DCs in the peripheral tissues are highly phagocytic. Once they have phagocytosed pathogens, they mature, becoming less phagocytic. Mature DCs then migrate to lymphoid organs, where they transmit information to T cells about the nature of the pathogen and the infected tissues.

2.2 Nonprofessional Phagocytes

In multicellular organisms, a significant amount of phagocytosis is carried out by nonprofessional phagocytes. These are usually fibroblasts or epithelial cells whose phagocytic function facilitates general processes such as maintenance of the extracellular matrix, response to injury, development of inflammation, and regulation of immune responses. Phagocytosis by these cells is also essential to specific processes such as maintenance of vision and clearance of apoptotic cells. Nonprofessional phagocytosis is also an important vehicle through which pathogens gain access to the intracellular space.

2.2.1 Renewal of the Sensory Retina

The retina is a part of the central nervous system directly exposed to external environmental stimuli. The outer segments of photoreceptors are damaged by oxidative stress and need to undergo a renewal process. Phagocytic cells of the retinal pigmented epithelium (RPE) contribute to retinal renewal by ingesting and degrading the spent tips of photoreceptor outer segments. RPE cells are the most active phagocytes in the body, ingesting approximately 25 000 to 30 000 discarded segments per day. Phagocytosis of rod

outer segment tips by RPE cells is vitally important for maintaining structural and functional integrity of the retina. When RPE cells are unable to perform this task, irreversible photoreceptor degeneration and blindness occur. RPE phagocytic defects are common in the aging eye and may contribute to age-related macular degeneration.

2.2.2 Clearance of Apoptotic Cells

As a part of normal growth and development, certain cells undergo programmed cell death, or apoptosis. In contrast to necrosis, which is a form of cell death that results from acute tissue injury, apoptosis is carried out in an ordered process that minimizes inflammation. Although apoptotic cells may be removed by monocytes and macrophages, nonprofessional phagocytes play an important role in the clearance of apoptotic cells. This is particularly true in tissues that undergo frequent remodeling, such as epithelial barriers, and tissues that have been subjected to trauma. While professional phagocytes often need to be recruited to these areas, nonprofessional phagocytes are already present, allowing for immediate recognition and removal of dead cells. The timely engulfment of apoptotic cells prevents the release of their potentially proinflammatory and proimmunogenic contents.

After a cell has undergone apoptosis, it breaks down into apoptotic particles with intact membranes. These particles have certain molecules on their surface, including lectins and the lipid phosphatidylserine (PS), which signal their readiness to be phagocytosed. Unlike phagocytosis of pathogens, which is followed by the release of inflammatory mediators, phagocytosis of apoptotic cells is immunologically ''silent'' in that it does not lead to the induction of inflammatory responses.

2.2.3 Phagocytosis and Pathogens

Phagocytosis is critical to the survival of many pathogens. It provides a means by which many pathogens can avoid circulating immune factors such as antibodies and complement (see Sect. 3.2.2). The host cell cytoplasm also contains nutrients and other factors that many pathogens require. For example, the food-borne pathogen *Listeria monocytogenes* induces its uptake into intestinal epithelial cells and utilizes host cell actin to travel from cell to cell without ever leaving the intracellular environment. By using actin polymerization to propel itself, *Listeria* can distend the plasma membrane of one epithelial cell to project into the plasma membrane of another. For further discussion of this topic, see Sect. 4.

3 Cell Biology of Phagocytosis

Phagocytosis requires stimulation of receptors on the surface of the phagocyte by ligands on a phagocytic target. The receptors activate a number of signaling pathways that together orchestrate rearrangement of the actin cytoskeleton, extension of the plasma membrane, and fusion to form a vacuole termed the *phagosome*. Several downstream signaling events regulate interactions of the phagosome with the endocytic pathway and the production of microbicidal molecules. An overwhelming number of signaling molecules participate in phagocytosis. This section will highlight several molecules involved in receptor function during phagocytosis, in the process of ingestion, in the process of phagosome maturation, and in the linkage of ingestion to specific cellular responses.

3.1 Models of Phagocytic Signaling

The signaling initiated by particle binding to a phagocyte receptor causes local changes in the plasma membrane that lead to internalization. It follows that signaling events during phagocytosis must be highly localized. Two models of signaling have been proposed to describe the spatial organization of the phagocytic response: the zipper model and the trigger model.

According to the ''zipper hypothesis'', phagocytosis requires repeated interactions between ligands on the target particle and receptors on the phagocytic cell. In this model, membrane protrusions of the phagocytic cell move over the target like a zipper, as ligands on the particle sequentially engage phagocyte receptors. An important feature of this model is that the membrane events that lead to engulfment must be very localized. Signaling is spatially confined to the region of the cytoplasm near the receptor. The phagocytic response is limited to the particle that initiates phagocytosis.

In contrast, the trigger model entails phagocytic signaling that is not entirely confined to the region of the cytoplasm near the stimulated receptor. Signaling may radiate from the receptor site. As a result, the phagocyte may not only engulf the particle that initiated engulfment but also nearby particles. Phagocytosis in this model does not require repeated interactions between the particle and phagocyte receptors. Particle binding results in a signal that is propagated through a region of cytoplasm to nearby receptors. Once this signal is above a certain threshold, it leads to particle engulfment. The first pseudopod formed is often enough to complete ingestion. Some bacteria enter cells by stimulating this kind of all-or-none response.

Subsequent to engulfment, the newly formed phagosome participates in a series of membrane fission and fusion events, a process called *phagosome maturation*. The locally guided signaling that leads to engulfment in zippering phagocytosis does not appear to guide phagosome maturation. If maturation were strictly locally regulated, then identical phagosomes should all mature alike. Instead, identical phagosomes do not always mature identically. This indicates that signals governing maturation are not strictly locally regulated, but are integrated over the entire organelle.

Numerous different receptors can stimulate particle ingestion; the cytoskeletal elements mediating internalization differ according to the receptor stimulated and the nature of the pathogen being internalized, and the intracellular fates of the particle can differ. Despite the complexity associated with different phagocytic mechanisms, all share a number of features: Particle internalization is initiated by the interaction of specific receptors on the surface of the phagocyte with ligands on the surface of the particle. This leads to the polymerization of actin at the site of ingestion, and the internalization of the particle. The internalized particle is contained in a membrane-limited phagosome that matures via fission and fusion reactions with the endosomal system. Maturation is completed as the phagosome fuses with lysosomes and the phagosomal contents are degraded. However, many pathogens are able to avoid this fate by altering phagosome maturation.

3.2 Recognition of the Phagocytic Target

Recognition of the phagocytic target can either be direct or indirect. Direct

recognition occurs through interactions between phagocyte receptors and components of the target cell wall. Indirect recognition occurs through the process of opsonization. Opsonization is the binding of host cell proteins (opsonins) to the surface of microbes, apoptotic cells, or cellular debris. Opsonins promote or enhance the binding of the particle to phagocyte receptors.

3.2.1 Direct Recognition

Professional phagocytes express a set of surface receptors that recognize invading organisms and dead or dying cells. These target motifs are called *pathogen-associated molecular patterns* (PAMPs). The phagocyte receptors that recognize PAMPs are called *pattern recognition receptors* (PRRs). A number of these receptors recognize specific features that differentiate the target from normal cells. For example, there are phagocyte receptors for lipopolysaccharide (LPS), a component of the gram-negative bacterial cell wall, for peptidoglycan of gram-positive organisms, β-glucans in many fungal cell walls, denatured proteins, and phosphatidylserine (a surface-exposed component of apoptotic cells). These receptors directly bind their ligands on the target and initiate signaling cascades that lead to their uptake.

Toll-like Receptors Toll-like receptors (TLRs) are PRRs important in innate immunity. TLRs are a family of receptors that recognize a variety of molecules specific to pathogens, including surface components such as LPS, peptidoglycan, and lipoteichoic acid. TLRs derive their name from the Drosophila protein, Toll, which is involved in early development and host defense in the fly. TLRs are widely expressed on both professional and nonprofessional phagocytes. TLRs are recruited to phagosomes containing ingested targets. However, there is no evidence that TLRs themselves initiate phagocytosis. Signaling through certain TLRs is thought to identify a pathogen and trigger a tailored immune response. Thus, it is likely that TLRs localized to phagosomes act primarily to identify the target and to transmit signals that may activate specific microbicidal mechanisms.

3.2.2 Indirect Recognition

The host immune response has evolved soluble proteins that recognize invading microorganisms and, in turn, are recognized by specific receptors on phagocytic cells. These serum proteins are called *opsonins*, from the Greek *opson*, meaning, "to prepare to eat." Opsonins increase the range of microbes recognized as potential pathogens, or cells recognized as damaged or defective, and they engage potentially more efficient mechanisms for clearance than occurs through direct recognition. The classic opsonins are antibodies and complement, for which there are various receptors on phagocytic cells.

Fc Receptor Fc receptors (FcR) bind to the Fc portion of antibody molecules. Receptors for IgA (FcαR) and IgG (FcγR) are expressed on professional phagocytes. Phagocytosis through FcγR has been extensively studied. The Fcγ receptors on human monocytes that activate phagocytosis are FcγRI, FcγRIIA, and FcγRIII. These receptors contain immune-tyrosine activation motifs (ITAMs) in their cytoplasmic domains, which initiate signaling for particle engulfment through the activation of tyrosine kinases.

Complement Receptor The complement component C3 is the second major opsonin in serum. During complement activation, C3 is first cleaved to C3b and then further to inactivated C3bi. C3b or C3bi fragments attach nonspecifically to the carbohydrate surface of pathogens. Phagocytes express receptors for both of these C3 fragments, and these complement receptors may initiate phagocytosis. Unlike Fc receptors, complement receptors are not competent for ingestion in unactivated cells. Phagocytes ingest C3-opsonized targets efficiently only after activation. Activation stimuli can be found at sites of infection and inflammation, indicating that complement receptor-mediated phagocytosis occurs primarily at these sites.

Complement receptors 3 and 4 (CR3 and CR4) mediate ingestion of particles, while complement receptor 1 (CR1) is primarily responsible for adhesion of the opsonized target to the phagocytic cell. CR3 has a central role in PMN phagocytosis, and its expression is required for other receptors to interact appropriately with the cytoskeleton for adhesion and ingestion. The importance of this receptor in PMN function is highlighted by the phenotype of individuals with leukocyte adhesion deficiency type I, who lack the $\beta 2$ chain of CR3. These patients have severe recurrent infections due to failure of PMNs to migrate to the site of infection and failure of the few cells that do reach the site of infection to phagocytose efficiently.

CR3 and CR4 are integrin receptors that link to the cytoskeleton through their cytoplasmic tails. Their role in phagocytosis may be linked to their effects on the cytoskeletal organization of phagocytes. These receptors also activate tyrosine kinases that are essential for particle engulfment.

3.3 Early Signaling Events in Phagocytosis

When FcRs are ligated and clustered, tyrosine kinases are activated. ITAM-mediated activation of FcRs requires the tyrosine kinase Syk. Syk is required for FcR-mediated ingestion, but not CR3-mediated phagocytosis. Syk activation requires phosphorylation of the tyrosines within the ITAM, and, in many cases, members of the Src family of tyrosine kinases perform this function. However, genetic deletion of Hck, Fgr, and Lyn, three of the major Src family kinases of macrophages, delays but does not inhibit FcR-mediated phagocytosis. It is possible that Syk can phosphorylate the ITAMs itself when the receptors are sufficiently clustered.

A number of signaling events relevant to phagocytosis occur as a result of Syk activation. Syk can act not only as a kinase but also as a docking molecule for other signaling effectors. Syk activation leads to actin polymerization through the activation of phosphatidylinositol 3-kinase (PI-3 kinase), Rho family guanosine triphosphatases (GTPases), and p21-activated kinase. Syk also leads to the activation of phospholipase C (PLC), which, in turn, activates protein kinase C (PKC).

PI-3 kinase catalyzes the phosphorylation of phosphatidylinositol (PI) $(4,5)P_2$ to $PI(3,4,5)P_3$, a phospholipid important in recruiting signaling molecules such as the kinase Akt/PKB to specific regions of the membrane. Inhibition of PI 3-kinase blocks phagocytosis of a broad spectrum of particles that include IgG- and complement opsonized particles and bacteria, clearly demonstrating an important role for PI-3 kinase activation in particle internalization. Blockade of PI-3 kinase does not inhibit particle binding or actin polymerization beneath the particle, which

suggests that phagocytic signaling is intact. Instead, PI-3 kinase is required for membrane extension and fusion behind the particle, perhaps by regulating the insertion of new membrane at the site of particle internalization.

PLC cleaves $PI(4,5)P_2$, releasing inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG activates PKC, which participates in the formation of actin filaments beneath the site of particle binding. Like PI-3 kinase, PLC is recruited to phagosomes containing IgG-opsonized particles and inhibition of its activity blocks internalization. Unlike PI-3 kinase inhibitors, PLC inhibitors completely block the formation of actin filaments beneath the site of particle contact, strongly suggesting that the main role of PLC is to activate PKC.

Phagocytosis induces activation of small GTPases of the Rho family, Rho, Rac, and Cdc42 that regulate cytoskeletal rearrangements. FcR-mediated phagocytosis depends on Rac and Cdc42, while CR3-mediated uptake of particles activates Rho. Cdc42 and Rac coordinate actin polymerization through the activation of WASP (Wiskcott–Aldrich syndrome protein) and Scar/WAVE (WASP family Verprolin-homologous) respectively and the Arp2/3 complex, which together lead to actin polymerization and pseudopod extension. Rac is also involved in the assembly and activation of the phagocyte NADPH oxidase complex, which generates microbicidal reactive oxygen molecules. Rho is required for myosin-dependent cell contractility, which is morphologically similar to the mechanism of CR3-mediated phagocytosis.

3.4 Internalization

Particle internalization requires activation of a number of signaling pathways that together orchestrate rearrangement of the actin cytoskeleton, extension of the plasma membrane, and fusion to form the phagosome. The precise mechanism of internalization is remarkably heterogeneous and depends on the type of receptor or receptors that participate in particle recognition and on the nature of the particle. Thus, although FcR-mediated phagocytosis is initiated by membrane protrusions that extend around the particle, particles internalized through CR3 appear to sink into the cell without significant membrane protrusions. These differences are likely due to different cytoskeletal elements that are assembled at the site of phagocytosis.

FcR-mediated phagocytosis occurs through a zippering mechanism. Sequential ligation of FcRs by particle-bound IgG results in pseudopod extension over the particle (Fig. 1). Alterations in the actin cytoskeleton are essential for pseudopod extension during FcR-mediated phagocytosis. Pseudopod advance is followed by contractile activities that constrict the outer margin of these extensions to enclose the particle. Myosins are utilized for the contractile activity of phagosome closure. FcR-mediated phagocytosis results in a response proportional to the size of the particle, which results in the formation of a phagosome tightly apposed to the particle surface.

Phagocytosis mediated through CR3 occurs through a variation of the zipper method; it does not involve pseudopod formation, but rather C3-opsonized particles simply sink into phagocytes. In addition to the actin cytoskeleton, microtubules are required for CR3-mediated phagocytosis.

Several bacteria are internalized through methods very different from zippering phagocytosis. *Salmonella typhimurium* triggers generalized membrane ruffling that results in the internalization of

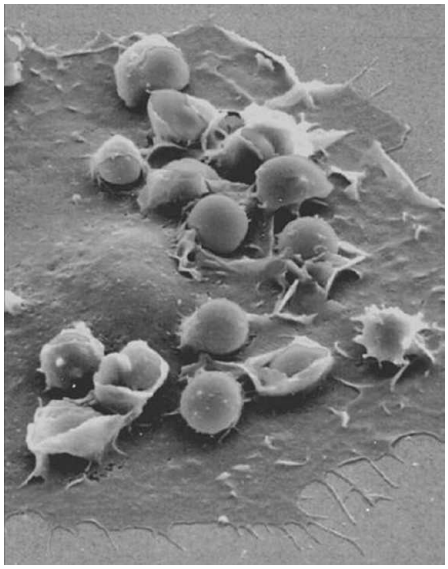

Fig. 1 Scanning electron micrograph of a macrophage internalizing IgG-opsonized erythrocytes.

the bacterium into a large compartment resembling a macropinosome (a large compartment of internalized extracellular fluid). The phagosome is large relative to the bacterium and has been called a *spacious phagosome*. *Legionella pneumophila* contains a surface protein that fixes complement to the surface of the bacterium, thereby facilitating binding to the macrophage surface through the CR. After binding, the bacterium induces the formation of an extended host cell pseudopod that spirals around the bacterium, forming a structure termed a *coiled phagosome*. Since this structure of this phagosome is very different than that induced by CR3, it is likely that additional *L. pneumophila* signals must be required.

3.5 Cytoskeleton in Phagocytosis

The cytoskeleton mediates a variety of essential biological functions in all eukaryotic cells. In addition to providing the structural framework around which cell shape and polarity are defined, its dynamic properties provide the driving force for cells to move. The changes in cell shape that occur during phagocytosis are dependent on reorganization of the actin cytoskeleton. The cytoskeleton also serves as a platform to bring surface receptors, enzymes, and their substrates into close proximity. Thus, agents that depolymerize the cytoskeleton not only inhibit shape changes but also inhibit signals initiated by receptor ligation.

All types of phagocytosis require myosins and actin polymerization at the site of ingestion. Myosins have been localized to phagosomes and play a key role in phagosome formation. Actin polymerization generates the force necessary for particle engulfment during phagocytosis. This is particularly evident in FcR-mediated phagocytosis during which a band of filamentous actin (F-actin) moves over the particle during pseudopod extension. Subsequent to FcR activation, localized actin polymerization occurs underneath the phagocytic target and promotes assembly of a continuous F-actin cup. In contrast, CR3-mediated internalization leads to the transient accumulation of F-actin and cytoskeletal elements in small foci underneath bound particles. Although phagocytosis mediated through FcR and CR3 both require actin, only phagocytosis mediated by CR3 is sensitive to agents that disrupt microtubules. This difference may account for the different mechanisms of internalization initiated by the receptors.

The cytoskeleton also plays a part in phagosome maturation. Microtubules are required for positioning of various

components of the endocytic pathway in defined domains of the cell and for organelle motility. Microtubules provide the substrate for motor proteins, dynein, and kinesin, which propel organelles in specific directions along the length of the microtubule. Microtubule-based motility contributes to phagosome maturation, as disruption of microtubules can slow fusion of phagosomes with lysosomes.

3.6 Phagosome Maturation in Macrophages

The internalization of a particle into a membrane-limited vacuole creates a new intracellular organelle, the phagosome. In order to progress to the hostile environment required for degradation, the phagosome must be completely remodeled, a process termed *phagosome maturation*. As the phagosome matures within the macrophage, both its membrane composition and contents are modified through sequential interactions with the endocytic pathway. The process occurs differently in neutrophils, which have a small endocytic compartment and specialized lysosomes called *primary granules*. Primary granules fuse directly with the base of the phagosome as it develops.

3.6.1 The Endocytic Pathway of Macrophages

The endocytic pathway is a series of intracellular vesicular organelles, distinguishable by their membranes and contents. Within the endocytic compartment, molecules mix and redistribute by organelle fusion and cytoskeleton-associated organelle motility. The distinct identities of the compartment organelles are maintained during this mixing by segregation of membrane molecules, together with vesicle fission reactions that restore or maintain compartment identities.

The endocytic pathway consists of endosomes and lysosomes. Endosomes are acidic organelles that receive internalized molecules from the plasma membrane, and sort them efficiently to other vesicular compartments, or recycle them back to the plasma membrane. There are early endosomes and late endosomes, which differ in membrane markers and luminal pH. Early and late endosomes have a characteristic pH of 6.5 and 6.0 respectively. Membrane markers of early endosomes include Rab5 and early endosome antigen 1 (EEA1), while Rab7 is a marker of late endosomes. Lysosomes are distinguished from endosomes by a pH of 5.0 to 5.5 and the presence of acid hydrolases. Lysosomes are the terminal degradation compartment of the endocytic pathway.

3.6.2 Membrane Traffic in Phagosome Maturation

The nascent phagosome membrane was originally thought to be similar in composition to the plasma membrane, containing a sample of the extracellular medium. Recent analyses of phagosomes containing latex beads identified a number of membrane proteins that typically reside the endoplasmic reticulum (ER). The presence of these proteins on phagosomal membranes indicated that the ER contributes membrane to the forming phagosome.

After internalization, phagosome maturation is temporally coordinated through the sequential activities of molecules that direct fusion with elements of the endocytic pathway. Rab GTPases and phosphoinositides regulate diverse functions associated with membrane trafficking, such as vesicle formation, vesicle docking and fusion, and organelle association with the cytoskeleton. Rab5 directs interactions of

the phagosome with early endosomes and recruits the type III PI-3 kinase hVps34, which generates PI(3)P. Rab5 and PI(3)P are present on the phagosomal membrane at early time points and may facilitate the assembly of the NADPH oxidase complex on early phagosomes.

Rab7 is acquired by phagosomes during the progression from the early to late endosomal stages. Rab7 is an important regulator of membrane transport from early to late endosomes and of lysosome biogenesis. Late-stage phagosomes fuse with lysosomes to form a hybrid organelle in which the phagosomal contents are degraded by acid hydrolases.

3.6.3 Production of Microbicidal Molecules within Phagosomes

In concert with phagosomal maturation, there is a progressive acidification of the interior of the phagosome. The drop in pH occurs as a result of the acquisition of the vacuolar proton-ATPase to the phagosome, which actively pumps protons into the phagosome. The acidic lumen can inhibit bacterial growth and viability, and enhance other microbicidal mechanisms within phagosomes. For example, low pH can activate pH-sensitive proteases and lipases that are delivered to the phagosome during fusion with lysosomes. Creating an inhospitable environment for pathogens may not be the only role of phagosomal acidification. The lumenal pH contributes to membrane traffic. Inhibition of phagosomal acidification prevents phagosome-lysosome fusion.

Microbicidal anions are also produced within phagosomes. The presence of Rac and PI(3)P on early phagosomes facilitates the assembly of the NADPH oxidase complex on early phagosomes. Activation of NADPH oxidase does not occur as a result of CR3-mediated phagocytosis, as CR3-mediated uptake of particles activates Rho, but not Rac. NADPH oxidase catalyzes the production of superoxide anion. Superoxide can interact with chelated metals to produce hydroxyl radical or dismutate to hydrogen peroxide, from which additional reactive oxygen intermediates (ROI) are generated. ROI are potent cytotoxic molecules, which damage bacterial DNA and membranes. The critical importance of ROI generation by NADPH oxidase in immunity to microbes is emphasized by the symptoms of patients with chronic granulomatous disease (CGD), a genetic deficiency in any of the NADPH oxidase subunits. The hallmarks of CGD are recurrent bacterial infections and chronic inflammation with granuloma formation.

Superoxide and hydrogen peroxide, in addition to their own antimicrobial activity, can also be used as substrates for the neutrophil enzyme, myeloperoxidase. Myeloperoxidase is stored in the granules of neutrophils and is also expressed in monocytes. Using the products of NADPH oxidase as its substrates, myeloperoxidase generates hypochlorous acid as well as other ROI, all of which have potent microbicidal activities.

Cytotoxic reactive nitrogen intermediates (RNI) are also produced inside phagosomes of mouse macrophages activated by interferon gamma and LPS. Inducible nitric oxide synthetase localizes to vesicles and produces nitric oxide (NO) from L-arginine. NO is toxic to bacteria, as it damages membranes, and inactivates DNA and proteins. Superoxide and NO can combine to produce another microbicidal molecule, peroxynitrite.

4
Microbes and Phagocytosis

Phagocytosis evolved, in part, as a defense mechanism against pathogenic microorganisms. In turn, pathogenic bacteria have evolved methods that avoid destruction by phagocytes. Some bacteria avoid phagocytosis, while others survive within phagocytes. Paradoxically, many pathogens actually stimulate cells to initiate phagocytosis, and thrive in the intracellular environment (see Fig. 2).

4.1
Evasion of Phagocytosis

Phagocytosis requires binding of the particle by phagocyte cell surface receptors. *Streptococcus pyogenes* avoid phagocytosis by producing a slippery capsule, which phagocytes cannot grasp. The capsule also prevents opsonization by antibodies or complement. Other pathogenic bacteria have evolved mechanisms to regulate Rho family GTPases as a means of avoiding immune clearance. *Yersiniae* species avoid phagocytosis by host immune cells in part by secreting a protein called YopE into the cytoplasm of host cells. YopE rapidly deactivates Cdc42, Rac, and Rho, thereby inhibiting the actin rearrangements necessary for phagocytosis.

4.2
Induction of Phagocytosis

Many pathogens can evade immune destruction by taking advantage of the phagocytic uptake of apoptotic cells. The parasite

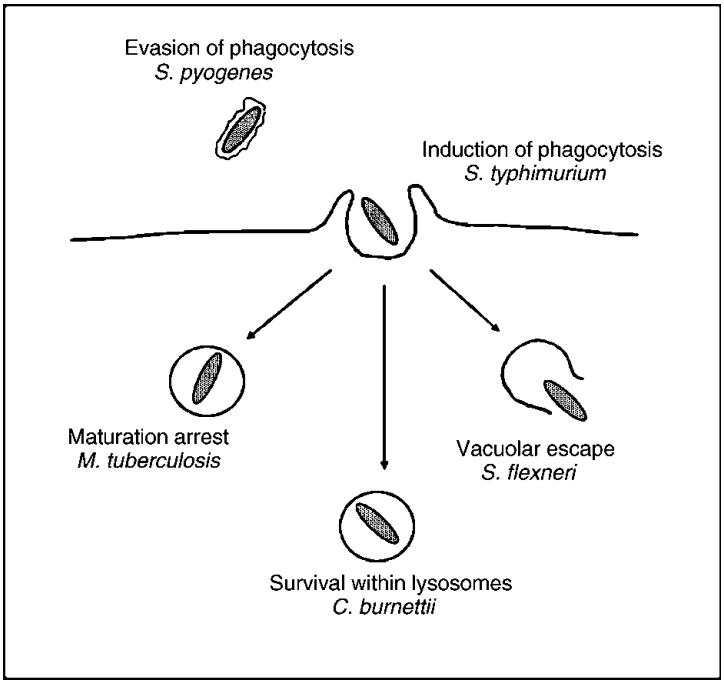

Fig. 2 Bacterial mechanisms for escaping phagocytic clearance. Selected examples of bacteria that use the indicated mechanisms are given.

Trypanosoma brucei induces apoptosis in host cells and is engulfed along with the apoptotic particles into new host cells. *Leishmania* spp are obligate intracellular parasites; that is, they must reside inside cells for survival. To reach the intracellular environment, these parasites mimic apoptotic cells by expressing PS on their outer membranes; they are phagocytosed by macrophages.

Many pathogens, such as *L. monocytogenes,* induce their uptake into host cells by directly engaging receptors on nonprofessional phagocytes. In this way, they can gain intracellular entry by receptor-mediated phagocytosis using receptors normally used for adhesion or growth control. Others, such as *Escherichia coli* and *Salmonella*, secrete factors that can selectively induce phagocytosis. Commonly, pathogens induce phagocytosis by triggering signal transduction cascades leading to cytoskeletal rearrangements.

4.3 Intracellular Survival within Phagocytes

Subsequent to phagocytosis, pathogens may survive within phagocytes by modifying the normal membrane trafficking that accompanies phagosome maturation. Some bacteria halt phagosome maturation prior to phagosome–lysosome fusion, and others avoid the endocytic pathway all together. *Mycobacteria tuberculosis* prevent fusion of phagosomes with lysosomes by inhibiting the function of EEA1, an early endosome marker required for phagosome–endosome interactions. These bacteria also prevent phagosomal acidification by excluding ATP, an energy source required for the proton ATPase pump, from its limiting membrane. *Legionella* and *Chlamydia* phagosomes have little or no interaction with the endocytic compartment but instead reside in compartments derived from the endoplasmic reticulum and Golgi apparatus, respectively. Compartments containing *Chlamydia* are not microbicidal; they do not acidify and do not interact with lysosomes. *Legionella* phagosomes resemble autophagosomes, which eventually fuse with lysosomes.

A few intracellular pathogens avoid destruction within lysosomes by producing toxins that rupture the phagosome and allow the bacteria to survive within the host cell cytosol. In the safe cytosolic environment, these bacteria are ensured a neutral pH, ample access to nutrients, and protection from many of the host cell defenses by enzymes like superoxide dismutase and catalase that eliminate ROI. *Shigella flexneri* and *L. monocytogenes* are examples of bacteria that employ phagosomal exit as a survival strategy.

Instead of avoiding the lysosomal environment, some bacteria can survive within it. *L. pneumophila* and *Coxiella burnetii* are unique among intracellular pathogens, in that they thrive within the acidic environment of lysosomes. *C. burnetii* has an absolute requirement for the acidic pH to activate its metabolism.

5 Conclusions

Phagocytosis is a fundamental cellular process that serves multiple functions in tissue homeostasis and immunity. The targets of phagocytosis, their recognition motifs, the receptors essential for their uptake, and the intracellular signals necessary for their entry into phagosomes are as diverse as the biological processes to which phagocytosis contributes. The molecular mechanisms underlying phagocytosis are

just beginning to be uncovered. The mechanisms utilized by pathogens to modify the phagocytic pathway to their own advantage have provided useful information about the development of the phagosome. Further insights into the mechanisms of phagocytosis may suggest novel strategies for modulation of the immune response and treatment of human infection.

single nucleotide polymorphism (SNP)
Alteration of single base pair in DNA, leading to genetic mutations that may be associated with alterations in protein structure or expression.

Structure-based Drug Design
In silico drug design process where structure of ligand-binding site on protein is known.

Ligand-based Drug Design
In silico drug design process where activity data from a number of chemically distinct ligands are available – does not require protein structure.

The Human Genome Project is largely complete, so the problem facing scientists is how to maximize the use of the newly acquired data for improving health care. It is estimated that the number of therapeutic targets available for drug discovery will increase from the current number of 600 to 1000 to perhaps as many as 5000 to 10 000. In addition to the challenges that this number provides to the pharmaceutical industry, there is the issue of sequence variation through single nucleotide polymorphisms (SNPs), some of which may impact upon the way that the body handles drug treatment. This may be due to a direct effect on the binding site of the protein target through nonconservative alterations of the amino acid sequence, or else through indirect effects on drug metabolizing enzymes. In order to meet these challenges, the marriage of structural proteomics and computer-aided small molecule design will provide opportunities for creating new molecules *in silico*; these may be designed to bind to selected pharmacogenetic variants of a protein in order to overcome the nonresponsiveness of certain patient groups to a particular medicine. The basic aspects of these technologies, and their applicability to selected targets showing structural variation, form the basis of this chapter.

1
Introduction to *In Silico* Drug Design to Protein Targets

1.1
General Background

Much has been written concerning the expense and problems encountered by the modern pharmaceutical industry in developing novel drugs. As a further difficulty, the patient population (market) is becoming fragmented because of genetic variation in the response to medicines, resulting from alterations in the drug target or in the metabolism of the compound once ingested. The relatively new discipline of pharmacogenetics is concerned with the inheritance of these variations, measured using single nucleotide polymorphism (SNP) analysis at the level of genomic DNA. Pharmacogenomics, on the other hand, is relevant when the genetic variation leads to changes in protein expression or conformation of key ligand

binding sites. This may result in loss of drug efficacy due to lack of binding; when the loss of binding occurs in drug metabolizing enzymes, this may result in levels of compound in the blood that exceed safety thresholds.

While these aspects of human genetics are problematical for both patients and pharmaceutical companies alike (for obviously different reasons), there are ways forward; these are emerging from new drug discovery technologies, including *in silico* approaches to drug design. The relevant technologies will be described in this chapter, but first we shall discuss the background to lead discovery and pharmacogenomics by concentrating on the structural aspects of the protein targets for small molecule drugs.

1.2 The Need for Protein Structure Information

Traditional drug discovery has relied upon the chemical modification of biologically active natural products or high-throughput screening of compound libraries to obtain hits that may be converted to leads and ultimately drugs. This process is generally inefficient, since the nature of compound collections used for screening is often a reflection of the historical activity of the company in question. This means that most compounds will be limited in coverage of the variety of targets encountered in drug research, namely, enzymes, receptors, and ion channels. Even the advent of combinatorial chemistry in the mid-1990s has failed to deliver a noticeable increase in good drug leads.

The problems highlighted above have been compounded by the increase in targets afforded by the genome sequencing projects, culminating in the recent publications of the human sequence. The realization that it will be impossible to find suitable small molecule candidates for every potential drug target using high-throughput screening alone has driven the search for alternatives based on an understanding of the three-dimensional structure of the protein. The structural information on the ligand-binding site may then be used for the *in silico* design of compounds that make strong interactions with appropriate residues within these sites; alternatively, existing small molecule structures may be docked into the sites and optimized using medicinal chemistry techniques.

The availability of three-dimensional protein structures is clearly one of the rate-limiting steps in this process. Publicly available structures, derived by X-ray diffraction or NMR techniques, are deposited in the protein data bank (PDB), and currently number over 20 000 entries. There is considerable redundancy in this, however, with the number of single entries for human proteins being considerably less. Owing to the technical difficulties associated with certain classes of protein there is a strong bias toward enzymes in the database. This excludes, therefore, the G-protein-coupled receptors (GPCR) and ion channel classes that make up a large proportion of drug targets. A number of public and private structural proteomics initiatives have been established in order to increase the number and variety of structures that may be used for studies of protein folding or drug discovery. Where structures are not available, it is possible in many instances to create a homology model using the structure of a related protein as a guide. The success of drug design corresponds to

the percentage identity between the sequence and the known structure. Despite these advances (including the structural determination of the GPCR rhodopsin, it has to be accepted that some proteins will not yield to current structural techniques. This does not mean, however, that *in silico* drug design techniques cannot be used with these proteins, since ligand-based design can be employed (see Sect. 3.3).

1.3 Protein Structure and Variation in Drug Targets – the Scale of the Problem

Variation in the response of individual patients to medicines is an important issue that is currently being addressed by the pharmaceutical industry. It would be useful to have some idea of the scale of the problem by determining the number of SNPs in the human genome and their relative effects on both the level of expression and functional activity of the protein target. From the perspective of rational drug design, it is necessary to consider the alteration of the tertiary structure of the translated protein in which function is retained, but not the binding of an existing drug. This is directly analogous to the situation with the microbial targets (e.g. HIV reverse transcriptase) in which sequence variations affect the structure of the target, resulting in the problem of drug resistance.

An analysis of 1.42 million nonredundant human SNPs has been recently published by an international collaborative group. The majority of these are in repetitive regions, whereas 60 000 lie within coding and untranslated regions of exons. Bearing in mind that many more SNPs are being identified in the public and private domains, the total number that are potentially able to disrupt protein structure, while small in comparison with the total genome complement, is still likely to be significant in terms of pharmaceutical research opportunities. This study gave an overview of the total number of SNPs available within the public domain as of the first quarter of 2001.

An analysis of polymorphisms in coding regions was published by Landers group in 1999. They identified 560 SNPs (392 in coding regions) in 106 genes of relevance to cardiovascular disease, neuropsychiatry, and endocrinology. Only a minority of polymorphic changes gave rise to nonconservative amino acid substitutions, most likely due to evolutionary selection against deleterious mutations in the human genome.

Nevertheless, there is considerable activity in identifying SNPs within protein targets for current marketed drugs. The whole purpose of the study of genetic variations in drug responses is to identify patients who may benefit from a particular medicine and avoid wasteful (or dangerous) prescription to others. Examples of drug targets and detoxification systems that have been studied using SNP or other mutational analyses are listed in Table 1.

These comparatively early studies are beginning to highlight a number of points, including the fact that some SNPs are specific for particular ethnic populations. In addition, some drug targets appear not to have amino acid sequence variation as a result of SNP polymorphism, and therefore will not require a number of different ligands to accommodate this. However, since variations in tertiary structure resulting from mutations in the coding region offer opportunities for structure-based design, some relevant examples will be discussed in detail below.

Tab. 1 Examples of SNPs that influence drug metabolism or disease state.

Drug target	*Disease*	*Comments*
NMDAR1 receptor	Schizophrenia	SNPs in coding region, but no functional significance
Quinone oxidoreductase, Sulfotransferase	Drug metabolism	6 out of 22 coding region SNPs gave amino acid substitutions
75 candidate genes for blood pressure homeostasis	Hypertension	874 candidate SNPs with 387 within coding sequence; 54% of these predicted to change protein sequence
Thiopurine *S*-methyltransferase	Drug metabolism	SNPs in promoter region, introns, and 3′UTR, but not coding region
41 candidate genes	Ischemic heart disease	SNPs restricted to ethnic group (Japanese) used in study
CYP3A	Drug metabolism	SNPs cause alternative splicing and protein truncation
β_2-adrenergic receptor	Asthma	SNPs cause alteration of ligand binding
BCR-ABL tyrosine kinase	Cancer	Point mutation causes resistance to STI-571 compound

Mutations in Drug Targets Leading to Changes in the Ligand-binding Pocket

2.1
β_2-adrenergic Receptor

This well-characterized drug target for antiasthma medications represents one of the earliest examples of a natural mutation, leading to an alteration in ligand binding. Mutation of Thr164 to Ile in the fourth transmembrane-spanning domain of this G-protein-coupled receptor occurs at low frequency in the population tested, but gives rise to altered ligand binding through interaction with an adjacent Ser165, as illustrated in Fig. 1.

This example is one where the accurate three-dimensional structure of the protein is unknown; under these circumstances, it is necessary to create a computer model. The development of inhibitors that are designed to overcome the effects of this mutation could not be based on the

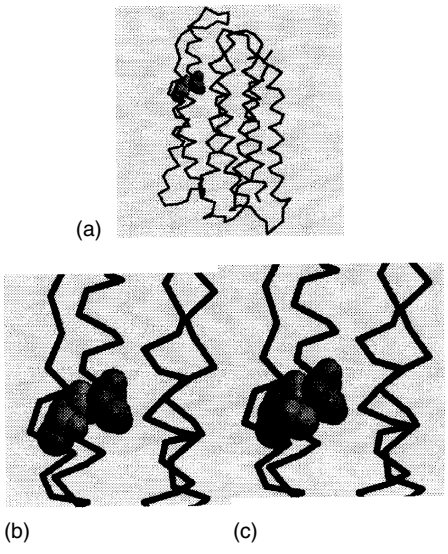

Fig. 1 Mutation of Thr164 to Ile in the fourth transmembrane region of the β_2-adrenergic receptor leads to steric interference with Ser165 within the active site of the receptor. (a) General domain structure and position of the residues, (b) wild type, (c) mutant showing interaction of Ile164 with Ser165.

accurate structure of a ligand-binding site; here, ligand-based design would be appropriate (see Sect.3.3).

2.2 STI-571 and BCR-ABL

STI-571 is a 2-phenylamino pyrimidine chemotherapeutic agent that targets the tyrosine kinase domain of the BCR-ABL oncogene present in chronic myelogenous leukemia (CML). After many years of research into compounds that are selective for specific oncogenes, this compound is showing real clinical benefit against CML. Unfortunately, due to the selective pressure on tumor cells to evolve resistance, a specific mutation in BCR-ABL inhibits the action of STI-571. Since crystal structures of ligand bound into the wild-type protein are available (PDB: 1IEP), it is possible to visualize the effects of a C-T nucleotide mutation, resulting in a substitution of Thr315 by Ile (Fig. 2). The change of amino acid results in disruption of a key hydrogen bond between oxygen on the threonine and a secondary amine nitrogen on STI-571.

In this example, structure-based design of inhibitors to the mutant enzyme may be undertaken using available X-ray structures and homology models.

2.3 Resistance to Human Immunodeficiency Virus (HIV)

The human retrovirus HIV can be controlled using chemotherapy directed at the reverse transcriptase and aspartyl protease

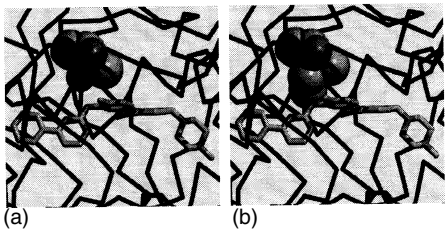

Fig. 2 Mutation of Thr315 (a) to Ile (b) in BCR-ABL interferes with the binding of STI-571.

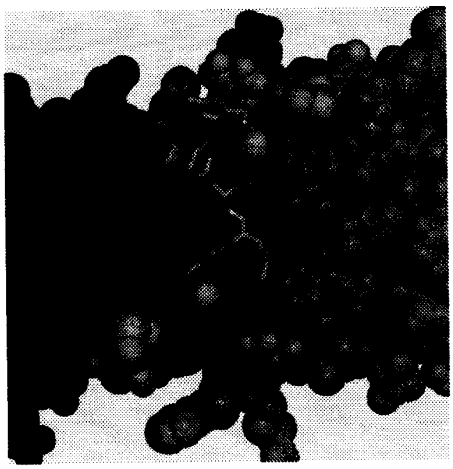

Fig. 3 Binding of the HIV protease inhibitor ritonavir. Amino acids highlighted in cyan are mutated in resistant strains of the virus and tend to occur at the extremities of the inhibitor.

encoded by the viral genome; with other microbial pathogens, however, resistance to drug therapy becomes a major problem. Figure 3 shows a crystal structure (PDB: 1HXW) of the HIV protease, where mutated amino acids (shown in cyan) lead to disrupted binding of the clinically effective inhibitor ritonavir.

3
In Silico Design of Small Molecules

Changes induced by SNPs (or other mutations) in the protein targets of drugs may result in the medicine being ineffective. In this case, the relevant disease may remain untreated, or else an expensive drug discovery effort will have to be undertaken to identify new molecules that are able to affect the mutant protein. Given that most current small molecule discovery strategies rely on expensive high-throughput screening and lead optimization programs, this is an unattractive prospect. Advances in computer-aided design, however, may make this process more efficient and less costly through creation of virtual small molecules that can by optimized for interaction with the mutant protein before any chemical synthesis is undertaken. The remainder of this chapter will be concerned with an overview of this exciting and rapidly evolving area of research.

3.1
Automated Drug Design Methods

The pharmaceutical industry faces a large increase in the number of therapeutic targets available for exploration. New methods must be developed for drug discovery that can be automated, are cheap, and that optimally explore the chemical space available for drug design. The number of different possible chemical structures has been estimated to be of the order 10^{200}, with perhaps 10^{60} structures with drug-like properties; these numbers can be compared with the estimated mass of the visible universe at 10^{56} g. Thus, it would not be possible to make a single gram of each potential drug molecule. In contrast, the number of different chemical structures synthesized is small by comparison, and has not yet reached 10^{8}. Clearly, *in silico* methods will have to be developed to cope with searches through the vastness of chemical space.

Design paradigms fall into two types:

- Structure-based methods that use three-dimensional structural information about the site.
- Ligand-based methods that can be used for drug discovery in the absence of structural information.

The applicability of structure-based methods is critically dependent on the availability of relevant structural data. The Structural Genomics Initiative is an international project that seeks to provide high-quality crystalographic or NMR data about new proteins. While promising for future drug discovery efforts, the rate of introduction of new structures into the public domain is still too slow. To speed this up, alternative methods for the generation of three-dimensional data using homology modeling techniques have been introduced. These are less precise, but show increasingly better performance, as elucidated by the computer-aided structure prediction (CASP) challenges (http://PredictionCenter.llnl.gov). The logical next step would be to automate protein structure prediction in order to provide extensive coverage of the human proteome. One of the main drivers for this

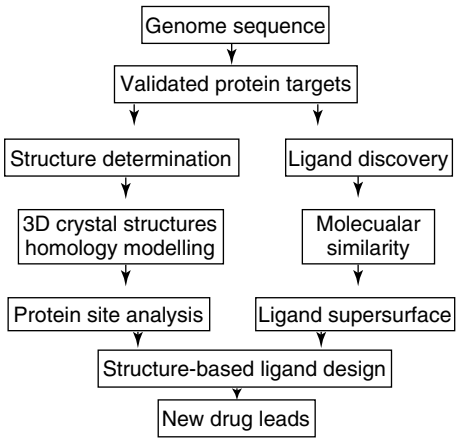

Fig. 4 Scheme for drug design utilizing genomic data. The left track illustrates the process of drug design based on structural_determination of binding sites. The right track outlines design from known ligands.

effort is the need for three-dimensional structural models of whole gene families for use in drug design.

Ligand-based design methods are built upon identified molecular similarities in known active ligands. The similarity methods have to cope with finding unspecified partial molecular similarities within the ligand data sets for freely flexible ligands. There are often many solutions to molecular similarity and choices have to be made as to which one to use. Figure 4 summarizes the two approaches to drug design.

3.2 Structure-based Drug Design

The automation of structure-based design can be divided into key areas for development:

- identification of binding sites
- automated analysis of binding sites
- prioritization of strategies for design within sites
- *de novo* design of scaffolds (active templates)
- elaboration of scaffolds into combinatorial libraries.

The identification of binding sites can be initiated from protein sequence information. Many sites show conservation of structural motifs; for example, many enzymatic catalytic sites have highly conserved local sequences within a gene family. Many of these motifs can be identified at the annotation stage of ascribing a function to a novel gene. Furthermore, the identification of cofactor binding sites can also provide additional clues to function. At the moment, the prediction of the molecular structure of the substrate has not been solved precisely, although docking algorithms could provide clues for potential substrate fitting into binding sites.

Ligands bind to their sites through specific molecular interactions, including hydrogen bonds, electrostatic interactions, steric interactions, interactions through hydration, and hydrophobic interactions. This pattern lies at the surfaces of both ligand and binding site, so that complementary interactions are optimized for efficient binding. If the target proteins have 3D coordinate data, computer algorithms can be used to automatically analyze the binding features and categorize them on a grid map of the protein surface. The features mapped onto grid

points are known as site points. Structurally and functionally related proteins may then be compared by superposing the binding sites and aligning the pattern of chemical features. This facility is important in pharmacogenomics, where we may wish either to design compounds that bind to a class of sites within related proteins, or to design compounds specific for a particular member of the protein family. In the latter case, the aim is to acquire selectivity. Figure 5 illustrates the family of caspase enzymes; caspases 1, 4, and 5 form a separate group – the ICE subfamily, the rest are in the CED-3 subfamily.

The CED-3 subfamily shows very similar three-dimensional structures. Figure 6 shows the superpositions of the Cα atoms. The structural backbones of the proteins within the family are closely superposed.

The concept of dividing sites into a collection of site points for design provides a method for directing design to specific regions. In some respects, this process has parallels to drug design from pharmacophores, where a small number of points are used to search compound collections by virtual screening. Four-point pharmacophores provide three-dimensionality to the search. However, the number of site points encountered in a site, often about 30, creates a combinatorial problem for selection. Suppose that there are n site points; if r site point interactions are

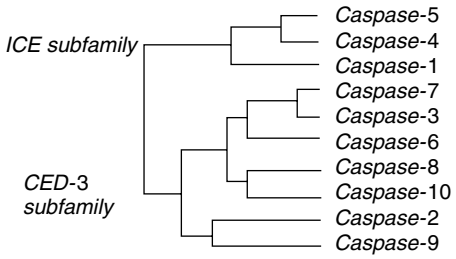

Fig. 5 Sequence similarities of the caspase family.

Fig. 6 Superposed Cα atoms from a selection of proteins in the CED-3 family of caspases.

needed for a molecule to have measurable affinity, the number of combinations of r site points, C(n,r) is given by $C(n,r) = n!/(r!(n-r)!)$ C(n,r) is a maximum when $r = n/2$. For the case where $n = 30$ and $r = 5$, there are 140 000 subsets of 5 site points. Each subset would be a strategy for design. However, some strategies would lead to preferred designs, for example, a strategy that included interactions with the catalytic residues would be expected to consistently perform well in designing inhibitors. Moreover, if there were crystallographic evidence of substrates or known inhibitors binding to certain residues, these would form a basic set for *de novo* design. Other methods for prioritizing design strategies could be built on hydrogen bonding regions, where there are overlaps in hydrogen-bonding probability. In the pharmacogenomic problem of design within a family of sites, the choice of design strategy is paramount for obtaining selectivity. The selection of site points should be such that the set chosen for the target protein should be as different as possible from nearly corresponding sets within the family of proteins.

The affinity of the designed drug molecule for its site is governed by the free energy of interaction DG. DG can be determined experimentally from the equation $\Delta G = -RT \ln K_b$ where K_b is the experimental binding constant, R is the gas constant and T is the temperature. The free energy has an enthalpic and entropic component $\Delta G = \Delta H - T\Delta S$ where ΔH is the change in enthalpy on binding and ΔS is the change in entropy.

De novo methods for drug design attempt to build novel molecules within specified regions of the site. Given the large number of molecules that could be created, it is important to assess the relative differences in predicted binding affinity for the designed ligands and the site. This is achieved using a scoring function based on the equations described above.

A composite scheme for *de novo* design is shown in Fig. 7.

Molecules are built from small molecular fragments, the latter being derived from databases of drug molecules such as the World Drug Index, or from proprietary compound collections. Fragments are labeled for attachment and substitution positions. Molecules are then built into the site by a stochastic assembly process from randomly selected fragments. This process is controlled by chemical rules that govern the addition, removal, or exchange of a fragment on the evolving skeleton. At each modification, the assembled structure is fitted in the site by positional and conformational transformations, with the scoring function being

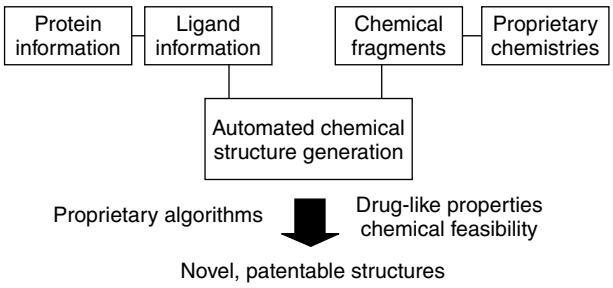

Fig. 7 Scheme for *de novo* design.

used to monitor the prediction of the free energy of the interaction between ligand and site. An optimal assembly procedure is performed using combinatorial optimization routines, such as simulated annealing or genetic algorithms.

Simulated annealing is an ergodic optimization method, meaning that, given sufficient time, the algorithm converges on the optimal solution irrespective of the initial starting position. If time constraints are placed on the algorithm run time, it behaves nonergodically and different solutions can be obtained that are acceptable, but suboptimal. In structure assembly, this is important, since a variety of molecular structures can be produced, thus giving a choice of different chemistries. These solutions can be analyzed statistically to identify different classes of structures that fit a chosen starting strategy.

Constraints can be placed on the structure assembly to limit the size of the molecule being generated so that it can be used as a template for further decoration by combinatorial chemistry. Virtual combinatorial chemical libraries can be created round the designed template to explore regions close to where the template has been designed to bind. The in-site enumeration of combinatorial libraries designed for a particular site is very important for chemical genomics, since it offers a way of designing molecules to distinguish between mutational differences in a particular site.

3.3 Ligand-based Drug Design

In the absence of useful three-dimensional information about the site, the designer can only build novel molecular structures on the basis of molecular similarity with existing active molecules. Ligand-based design requires the resolution of a number of technical issues. These are itemized below:

- A set of molecules is needed to extract spatially distributed chemical features for inclusion in drug design.
- Structurally dissimilar, active molecules provide more information about the site than a series of active close structural homologs.
- The molecules in the initial ligand set may have numerous torsion angles, making identification of the active conformation difficult.
- The choice of molecular similarity procedure needs to be made from a wide variety of available methods, preferably including one that includes a search for partial molecular similarity. This allows a more useful set of similarities to be identified.
- Molecules within the ligand set could have different binding modes, which need to be identified before selecting a subset for a design strategy.
- Molecules within the ligand set, with similar binding modes, need to be superposed such that the site points inferred from the corresponding ligand points show common spatial positions.
- The constraining supersurface of the set of molecules needs to be constructed to provide limits for automated design procedures.
- Since there is no information about the site, a scoring function based on free energy methods cannot be used.

A molecular similarity method that is applicable to this method of design has recently been published as the algorithm SLATE. This algorithm takes a set of molecules and compares them in a pairwise fashion for molecular similarity. The

molecules are allowed to flex. In the case of potential hydrogen-bonding interactions between the ligand points and possible complementary site points, site points are projected from the ligand surfaces. Hydrophobic regions are handled as local regional centroids. The molecular description is reduced to a set of points with associated properties. These sets of points can be matched using distance geometry and the search optimized by simulated annealing through conformational space. The procedure generates a similarity matrix; partial similarity is handled by null correspondences.

An application of this procedure to the design of novel compounds for the histamine H3 receptor has been published. Similarity data suggested that four hydrogen-bonding site points, together with two lipophilic regions, could be identified with a common spatial distribution. Furthermore, the constraining supersurface showed strong similarity with each of the selected ligand conformations. From these *in silico* designs, histamine H3 antagonists were synthesized and showed high affinity for the site. Thus, computational methods could be used to design potent ligands without any prior knowledge of the sequence or structure of the receptor.

4 Future Directions

New developments in pharmacogenomics will impact on drug design at three main levels:

- The interaction of the drug with its receptor binding site
- The absorption and distribution of the drug
- The elimination of the drug from the body.

If we are ever to achieve personalized drug therapies, the above issues will have to be addressed.

The bulk of this chapter has discussed SNPs in terms of mutated drug binding sites and the resulting changes that occur in response to medicines. In each of these cases, drug design strategies may need to be modified to develop drug molecules that would be selective and effective in the mutated site.

Absorption, in general, is treated as a physicochemical-transport process based on computations of logP (the octanol/water partition coefficient) and solubility governed by factors such as polar surface area on the molecule. It is conceivable that SNPs in drug transporter genes will affect the pharmacokinetic properties of compounds and, therefore, these may have to be taken into consideration in the design process.

Elimination mechanisms may include active excretion of drug molecules from cells, as with multiple drug resistance that arises in cancer chemotherapy. Patients with genotypes for particular MDR pathways could be identified and alternative treatments provided. Pharmacogenetic differences in the response to drugs can often be related to population differences in drug metabolizing enzymes. Crystal structures or homology models of these enzymes can be used to screen compounds designed *de novo* before synthesis has begun. This can be done at two levels: The virtual compounds can be input into metabolism prediction programs, such as Metabolexpert or Meteor, to identify principal pathways of expected drug metabolism. The virtual compounds can be screened against structural models of the metabolizing enzymes, including the known SNP variants. These procedures are becoming widely adopted

for the cytochrome P_{450} isozymes involved in oxidative drug metabolism.

Genomic prescreening of patients for SNP mutations in drug metabolism will improve the utility of clinical trials by focusing attention on the response of specific subpopulations to drug treatment. The consequence of this approach is that it should be possible to industrialize the creation of individual therapies, although at a significant increase in cost.

Pharmacogenomics will have a major influence on drug discovery, through drug design, as well clinical practice. The subtle changes in biomolecular structure caused by small SNP-induced amino acid alterations will profoundly affect the search for personalized medicines. In the future, greater emphasis will be placed on very precise differences in drug structures that select between mutated proteins. Along with being scientifically challenging, this approach will clearly have significant economic effects on the pharmaceutical industry.

Keywords

Biotech Drug
Biotechnologically derived drug products including proteins, peptides, antibodies, and antibody fragments, as well as antisense oligonucleotides and DNA preparations for gene therapy.

Absorption
Process by which the unchanged drug proceeds from the site of administration to the systemic circulation, that is, the blood or plasma compartment.

Distribution
Reversible transfer of drug between different organs, tissues, and fluids within the body.

Elimination
Irreversible loss of drug from the systemic circulation, that is, the blood or plasma compartment. Elimination comprises excretion and metabolism.

Excretion
Irreversible loss of chemically unchanged drug from the body.

Metabolism
Sum of all chemical reactions involved in biotransformation of a drug, that is, conversion of one chemical species into another within a living organism.

Clearance (CL)
The hypothetical volume of blood or plasma from which the drug is cleared per time unit by elimination mechanisms.

Volume of Distribution (V_d)
The hypothetical volume of a biological fluid that would be required to dissolve the total amount of drug within the body to achieve the same concentration as that found in

blood or plasma. It is a proportionality constant relating the amount of drug in the body to the concentration measured in the systemic circulation, that is, the blood or plasma compartment. Volume of distribution provides some general information about a drug's extent of distribution into body tissues. Together with clearance, it determines the elimination half-life $t\frac{1}{2}$ of a drug (*via* $t\frac{1}{2} = 0.693 \times V_d/CL$).

Exposure /Response Correlation
The relationship between exposure and response to a drug. Exposure comprises drug input to the body as quantified by acute or integrated measures of drug concentrations in blood, plasma, or other biological fluid. Response includes biomarkers, potential or accepted surrogate endpoints and short-term or long-term clinical effects related to either efficacy or safety.

PK/PD Model
A mathematically defined relationship between dose, concentration, and effect of a drug in a biological system. Pharmacokinetic/pharmacodynamic (PK/PD) modeling links the dynamic change in concentration over time as assessed by pharmacokinetics to what is, in most cases, the static relationship between the concentration at the effect site and the intensity of observed response as quantified by pharmacodynamics.

In recent years, biotechnologically derived peptide- and protein-based drugs have developed into mainstream therapeutic agents. Peptide and protein drugs, as well as oligonucleotides and DNA, now constitute a substantial portion of the compounds under preclinical and clinical development in the global pharmaceutical industry. The pharmacokinetic and pharmacodynamic properties of a biotech drug determine the relationship between administered dose, resulting systemic exposure, and subsequent pharmacologic response. Pharmacokinetics, and pharmacodynamics are, therefore, frequently crucial determinants of a drug's efficacy and safety, and their evaluation is an important component during the preclinical and clinical development of a drug candidate. However, pharmacokinetic and exposure/response evaluations for peptides and protein therapeutics are frequently complicated by their similarity to endogenous peptides and proteins as well as protein nutrients. In addition, pharmacokinetic/pharmacodynamic (PK/PD) correlations for biotech drugs are frequently convoluted by their close interaction with endogenous substances and physiologic regulatory feedback mechanisms. Extensive use of pharmacokinetic and exposure/response concepts in all phases of drug development has, in the past, been identified as a crucial factor for the success of a scientifically driven, evidence-based, and hence accelerated drug development process. Thus, PK/PD concepts are likely to continue and expand their role as a fundamental factor in the successful development of biotechnologically derived drug products in the future.

1 Introduction

In the last two decades, an increasing fraction of pharmaceutical R&D has been devoted to biotechnology-derived drugs (biotech drugs) – large molecules such as soluble proteins, monoclonal antibodies, and antibody fragments, as well as smaller peptides, antisense oligonucleotides, and DNA preparations for gene therapy. Biotech and genomics companies currently perform nearly one-fifth of all pharmaceutical R&D, a figure that is set to double within the next ten years. These biotech-related drug development efforts have so far been quite successful. Biotech products accounted for more than 35% of the 37 new active substances (NASs) that were launched in 2001, and it has been predicted that half of all NASs developed in the next 10 to 15 years will result from research into antibodies alone. Numerous approved biotech drug products have revolutionized pharmacotherapy in various indications, including erythropoietin (Epogen®, Procrit®), abciximab (ReoPro®), and trastuzumab (Herceptin®) to name only a few. Since the development of biotech drugs generally rests on a fundamental understanding of the related disease, their clinical development has also proven to be more successful than for conventional small molecules (new molecular entities: NCEs). Only 8% of the NCEs that entered clinical drug development between 1996 and 1998 reached the market compared with 34% in the case of biotech drugs. On the basis of these facts, it can be predicted that biotech drugs will play a major, if not dominant, role in the drug development arena of the coming decades. Thus, biotech-based medications might serve as the key for the aspired ''personalized medicine'' in the health care systems of the future.

The basis for the pharmacotherapeutic use of biotech drugs is similar to that for small molecules – a defined relationship between the intensity of the therapeutic effect and the amount of drug in the body or, more specifically, the drug concentration at its site of action, that is, the exposure–response relationship. The relationship between the administered dose of a drug, the resulting concentrations in body fluids, and the intensity of produced outcome may be either simple or complex, and thus either obvious or hidden. However, if no simple relationship is obvious, it would be misleading to conclude *a priori* that no relationship exists at all, rather than that it is not readily apparent.

The dose–concentration–effect relationship is defined by the pharmacokinetic (PK) and pharmacodynamic (PD) characteristics of a drug. PKs comprises all processes that contribute to the time course of drug concentrations in various body fluids, generally blood or plasma, that is, all processes affecting drug absorption, distribution, metabolism, and excretion. In contrast, PDs characterizes the effect intensity and/or toxicity resulting from certain drug concentrations at the assumed effect site. To put it simply, PKs characterizes ''*what the body does to the drug*,'' whereas PDs assesses ''*what the drug does to the body*.'' The combination of both pharmacological disciplines by integrated pharmacokinetic/pharmacodynamic modeling (PK/PD modeling) allows a continuous description of the effect-time course directly resulting from the administration of a certain dose (Fig. 1).

PK and PD principles are as applicable to biotech drugs such as peptides, proteins, and oligonucleotides as they are to

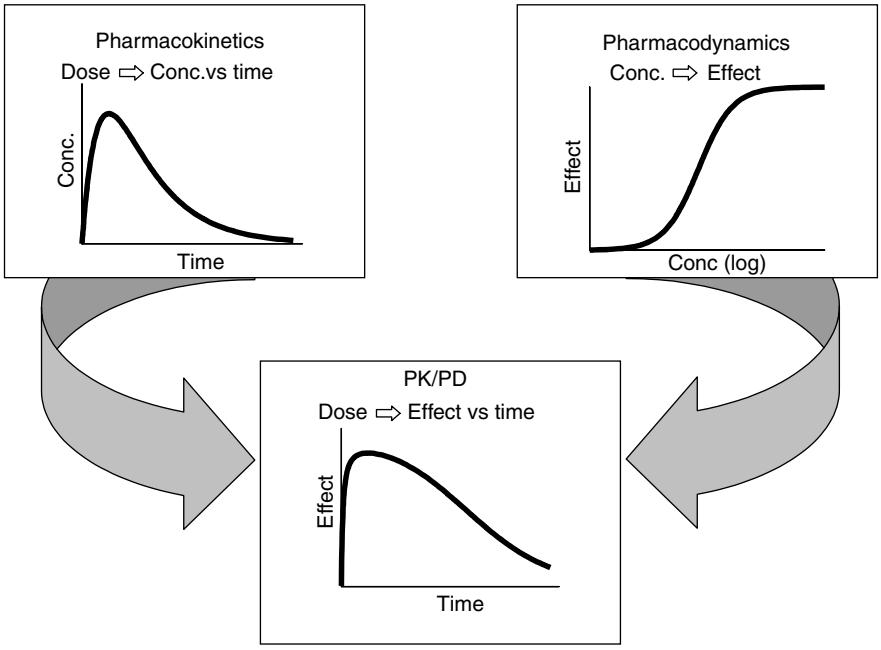

Fig. 1 Pharmacokinetic/pharmacodynamic (PK/PD) modeling as combination of the classic pharmacological disciplines, pharmacokinetics and pharmacodynamics (Reprinted with permission from Derendorf, H., Meibohm, B. (1999) Modeling of pharmacokinetic/pharmacodynamic (PK/PD) relationships: concepts and perspectives, *Pharm. Res.* **16**, 176–185).

conventional small-molecule drugs. These also include PK/PD related recommendations for drug development, such as the recently published exposure–response guidance document of the US Food and Drug Administration and the ICH E4 guideline of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use. Since biotech drugs are frequently identical or similar to endogenous substances, they oftentimes exhibit unique PK and PD properties. These may pose extra challenges and questions during their preclinical and clinical drug development that are different from small-molecule drug candidates and may require additional resources and unique expertise. Some of these problems and challenges will be discussed in the following text.

2 Bioanalytical Challenges

The availability of an accurate, precise, and specific bioanalytical technique for the quantification of active drug moieties in plasma, blood, or other biological fluids is an essential prerequisite for the evaluation of the relationship between dose, concentration, and effect of biotech drugs. In analogy to small molecules, these analytical techniques have to be validated and have to meet prespecified criteria regarding accuracy, precision, selectivity,

sensitivity, reproducibility, and stability – for example, those recommended by the US Food and Drug Administration. Additional requirements for bioanalytical method validation for macromolecules have recently been published.

A further level of complexity is often added to the bioanalytics of biotech drugs by the fact that many of these compounds are endogenous substances that are already in the body before drug administration. Thus, the analytical technique will detect a so-called baseline level prior to drug exposure. This baseline level can either be constant or undergo complex changes, for example, circadian rhythms or irregular time courses. In order to characterize the clinical pharmacology of biotech drugs naturally present in the body, baseline values have either to be accounted for in the PK and PD analysis or be suppressed before exogenous drug administration. The suppression of endogenous baseline levels is oftentimes facilitated *via* physiological regulation or feedback mechanisms. This approach was, for example, used to suppress the endogenous release of insulin and somatotropin (growth hormone, GH) *via* infusions of glucose and somatostatin respectively, prior to their exogenous administration for evaluation of their PKs.

In contrast to the bioanalytics of small-molecule drugs, immunoassays and bioassays are frequently applied to quantify peptides and proteins in biological samples. Immunoassays are considered to be the analytical method of choice for concentration determinations of peptides and proteins, as they can be performed relatively rapidly and easily. These generally comprise enzyme immunoassays as well as radioimmunoassays with poly- and monoclonal antibodies. While both techniques have a sufficient sensitivity and reproducibility, their specificity for the active drug compound to be quantified has to be carefully evaluated during the assay validation process. Immunoassays may be insensitive to relatively minor changes in the primary or secondary structure of proteins. For recombinant interferon-γ, for example, bioavailability was reported to be $>100\%$ for subcutaneous compared to intravenous administration, a finding that was produced by assay artifacts due to slightly modified degradation products. Other potential interferences with immunoassays include matrix effects, specific binding proteins, proteases, and cross-reactivity toward endogenous proteins.

Bioassays are frequently used as an alternative, or in addition to immunoassay techniques. Bioassays, in contrast to immunoassays, quantify not the pharmacologically active substance, but its biological activity, for example, in cell culture models based on cell differentiation, cell proliferation, or cytotoxicity, as well as gene expression assays or whole animal models. Frequent major problems with bioassays include a high variability in the measured parameters, lack of precision, and their time- and labor-intensive nature. Furthermore, bioassays oftentimes also lack specificity for the measured compound, as they may also detect the response to bioactive metabolites.

Because of some of the problems with bioassays and immunoassays, liquid chromatography (LC) based techniques are increasingly being applied as an alternative. While modern LC-based assays have a comparable sensitivity to immunoassays, they are oftentimes characterized by a higher selectivity. LC/mass spectrometry with matrix-assisted laser desorption ionization (MALDI) was, for example, used in *ex vivo* PK studies in combination with

enzyme-inhibition experiments to investigate the complex metabolism of dynorphin A1-13, a peptide with opioid activity, up to the fifth metabolite generation.

Biodistribution studies for peptides are frequently performed with radioactively labeled compounds. The radioactivity can be introduced either by external labeling with ^{125}I or by internal labeling of already present atoms, for example, *via* the addition of ^{3}H, ^{14}C, or ^{35}S radioactively labeled amino acids to cell cultures producing recombinant proteins. External labeling chemically modifies the protein, which may affect its activity and PKs. Internal labeling circumvents these potential problems, but has the disadvantage that radioactively labeled amino acids might be reused in the endogenous amino acid pool. Thus, when using radioactive labeling, it is generally necessary to investigate whether the physicochemical and biological properties of the proteins remain unchanged. In addition, it is crucial to determine whether the measured radioactivity represents intact protein, labeled metabolites, or the released label itself. Radioactivity that can be precipitated with trichloroacetic acid, for example, can be used to delineate active protein from released label and metabolites of small molecular weight.

3 Pharmacokinetics of Peptides and Proteins

Although traditional PK principles are also applicable for peptides and proteins, their *in vivo* disposition is, to a large degree, affected by their physiological function. Peptides, for example, which frequently show hormone activity, usually have short elimination half-lives, which is desirable for a close regulation of their endogenous levels and, thus, their function. By contrast, transport proteins like albumin or antibodies have elimination half-lives of several days, which enables and ensures the continuous maintenance of necessary concentrations in the bloodstream. The reported terminal half-life for SB209763, a humanized respiratory syncytial virus monoclonal antibody, for example, was reported as 22 to 50 days.

3.1 Absorption

Traditionally, the largest obstacle for successful pharmacotherapy with peptide and protein drugs is their delivery to the desired site of action. A clinically usable absorption of exogenously applied peptides and protein after oral application with conventional dosage forms is usually not present. This lack of systemic bioavailability is caused mainly by two factors: high-gastrointestinal enzyme activity and the function of the gastrointestinal mucosa as an absorption barrier. There is substantial peptidase and protease activity in the gastrointestinal tract, making it the most efficient body compartment for peptide and protein metabolism. Furthermore, the gastrointestinal mucosa presents a major absorption barrier for water-soluble macromolecules like peptides and protein. This is, at least for peptides, complemented by the functional system of cytochrome P450 3A and *p*-glycoprotein activity.

Because of the lack of activity of most peptides and proteins when orally administered, nonoral pathways have been utilized, in addition to parental administration. These pathways include nasal, buccal, rectal, vaginal, percutaneous, ocular, and pulmonary drug delivery. Drug delivery *via* these administration routes, however,

is also frequently accompanied by presystemic degradation processes. The bioavailability of numerous peptides and proteins is, for example, markedly reduced after subcutaneous, or intramuscular administration compared to their intravenous administration. The pharmacokinetically derived apparent absorption rate constant is thus the combination of absorption into the systemic circulation and presystemic degradation at the absorption site. The true absorption rate constant k_a can then be calculated as

$$k_a = F \cdot k_{app} \quad (1)$$

where F is the bioavailability compared to intravenous administration. A rapid apparent absorption rate constant k_{app} can thus be the result of a slow absorption and a fast presystemic degradation, that is, a low systemic bioavailability.

3.2 Distribution

Whole body distribution studies are essential for classical small-molecule drugs in order to exclude tissue accumulation of potentially toxic metabolites. This problem does not exist for protein drugs in which catabolic degradation products are amino acids recycled in the endogenous amino acid pool. Therefore, biodistribution studies for peptides and proteins are primarily performed to assess targeting to specific tissues as well as to identify the major elimination organs.

The volume of distribution of proteins is usually small and limited to the volume of the extracellular space because of their high molecular weight and the related limited mobility because of impaired passage through biomembranes. After intravenous application, peptides and proteins usually follow a biexponential plasma concentration–time profile that can best be described by a two-compartment PK model. This has, for example, been described for leuprorelin, a synthetic agonist analog of luteinizing hormone-releasing hormone (LH-RH), for clenoliximab, a macaque–human chimeric monoclonal antibody specific to the CD4 molecule on the surface of T-lymphocytes, and for AJW200, a humanized monoclonal antibody to von Willebrand factor. The central compartment in this model represents primarily the vascular space, and the interstitial space of well-perfused organs with permeable capillary walls, especially liver and kidneys, while the peripheral compartment comprises the interstitial space of poorly perfused tissues like skin and (inactive) muscle.

Thus, the volume of distribution of the central compartment in which peptides and proteins initially distribute after intravenous administration is typically 3 to 8 L, which is approximately equal to or slightly higher than the plasma volume (approximate body water volumes for a 70-kg person: interstitial 12 L, intracellular 27 L, intravascular 3 L). The total volume of distribution (V_d) is frequently 14 to 20 L, not more than twice the initial volume of distribution (V_c). This distribution pattern has, for example, been described for the somatostatin analog octreotid (V_c of 5.2–10.2 L, V_d of 18–30 L), the t-PA analog tenecteplase (V_c of 4.2–6.3 L, V_d of 6.1–9.9 L), and the glycoprotein IIb//IIIa inhibitor eptifibatide (V_c of 9.2 L). Active tissue uptake and binding to intra- and extravascular proteins, however, can substantially increase the volume of distribution of peptide and protein drugs, as, for example, observed with atrial natriuretic peptide (ANP).

There is a tendency for V_d and V_c to correlate with each other, which implies

that the volume of distribution is predominantly determined by distribution in the vascular and interstitial space as well as unspecific protein binding in these distribution spaces. The distribution rate is inversely correlated with molecular size and is similar to that of inert polysaccharides, suggesting that passive diffusion through aqueous channels is the primary distribution mechanism.

Distribution, elimination, and PDs are, in contrast to conventional drugs, frequently interrelated for peptides and proteins. The generally low volume of distribution should not necessarily be interpreted as low tissue penetration. Receptor-mediated specific uptake into the target organ, as one mechanism, can result in therapeutically effective tissue concentrations despite a relatively small volume of distribution. Nartogastrim, a recombinant derivative of the granulocyte-colony stimulating factor (G-CSF), for example, is characterized by a specific, dose-dependent, and saturable tissue uptake into the target organ bone marrow, presumably *via* receptor-mediated endocytosis.

3.3 Protein Binding

It is a general PK principle, which is also applicable to peptides and proteins, that only the free, unbound fraction of a drug substance is accessible to distribution and elimination processes as well as interactions with its target structure (e.g. receptor) at the site of action. Hence, the activity of a drug is better characterized by its free rather than total concentration if there is no constant relationship between the two.

Physiologically active endogenous peptides and proteins are frequently interacting with specific binding proteins that are involved in their transport and regulation. Furthermore, interaction with binding proteins may enable or facilitate cellular uptake processes and thus affect the drug's PDs. Specific binding proteins were, for example, described for IGF-1 (insulin-like growth factor), t-PA, interleukin-2, and somatotropin.

Six specific binding proteins were identified for IGF-1, with one binding at least 95% of IGF-1 in plasma. Since the binding affinity of IGF-1 to this binding protein is substantially higher than IGF receptors, the binding protein is assumed to have a reservoir function that protects the body from insulin-like hypoglycemia. Furthermore, the elimination half-life for bound IGF-1 is significantly longer than for free IGF-1, since only the unbound IGF-1 is accessible to elimination *via* glomerular filtration or peritubular extraction.

Somatotropin, another example, has at least two binding proteins in plasma. This protein binding substantially reduces somatotropin elimination with a tenfold smaller clearance of total compared to free somatotropin, and also decreases its activity *via* reduction of receptor interactions.

Apart from these specific bindings, peptides and proteins may also be non-specifically bound to plasma proteins. For example, metkephamid, a met-enkephalin analog, was described to be 44 to 49% bound to albumin, and octreotid is up to 65% bound to lipoproteins.

3.4 Elimination

Peptide and protein drugs are nearly exclusively metabolized *via* the same catabolic pathways as endogenous or dietetic proteins, leading to amino acids that are reutilized in the endogenous amino acid

pool for the *de novo* biosynthesis of structural or functional body proteins.

Nonmetabolic elimination pathways such as renal or biliary excretion are negligible for most peptides and proteins. Amino acids as well as some peptides and proteins such as immunoglobulin A, however, are excreted into the bile. For octreotid, biliary excretion is, at least in rat and dog, an important elimination pathway. If biliary excretion of peptides and proteins occurs, it generally results in subsequent metabolism of these compounds in the gastrointestinal tract (see Sect. 3.4.2).

The elimination of peptides and proteins can occur unspecifically, nearly everywhere in the body, or can be limited to a specific organ or tissue. Locations of intensive peptide and protein metabolism are liver, kidneys, gastrointestinal tissue, and also blood and other body tissues. Molecular weight determines the major metabolism site as well as the predominant degradation process (Table 1).

The metabolism rate generally increases with decreasing molecular weight from large to small proteins to peptides, but is also dependent on other factors like secondary and tertiary structure as well as glycosylation. The clearance of a peptide or protein describes the irreversible removal of active substance from the extracellular space, which also includes cellular uptake besides metabolism. Because of the unspecific degradation of numerous peptides and proteins in blood, clearance can exceed cardiac output, that is, >5 L min^{-1} for blood clearance and > 3 L min^{-1} for plasma clearance. Investigations of the detailed metabolism of peptides and proteins are relatively difficult because of the myriad molecule fragments that may be formed.

3.4.1 Proteolysis

Proteolytic enzymes such as proteases and peptidases are ubiquitously available throughout the body, but are especially localized in blood, in the vascular endothelium, and also on cell membranes and

Tab. 1 Molecular weight as major determinant of the elimination mechanisms of peptides and proteins. As indicated, mechanisms may overlap. Endocytosis may occur at any molecular weight range (Modified from McMartin, C. (1992) *Adv. Drug Res.* **22**, 39–106; Braeckman, R. (1997) Pharmacokinetics and pharmacodynamics of peptide and protein drugs, in: Crommelin, D., Sindelar, R. (Eds.) *Pharmaceutical Biotechnology*, Harwood Academic Publishers, Amsterdam, pp. 101–122).

Molecular weight	*Elimination site*	*Predominant elimination mechanisms*	*Major determinant*
<500	Blood, liver	Extracellular hydrolysis, passive lipoid diffusion	Structure, lipophilicity
500–1000	Liver	Carrier-mediated uptake Passive lipoid diffusion	Structure, lipophilicity
1000–50 000	Kidney	Glomerular filtration and subsequent degradation processes (see Fig. 2)	Molecular weight
50 000–200 000	Kidney, liver	Receptor-mediated endocytosis	Sugar, charge
200 000–400 000		Opsonization	α2-macroglobulin, IgG
>400 000		Phagocytosis	Particle aggregation

within cells. Thus, intracellular uptake is *per se* more an elimination rather than a distribution process. While peptidases and proteases in the gastrointestinal tract and in lysosomes are relatively unspecific, soluble peptidases in the interstitial space and exopeptidases on the cell surface have a higher selectivity and determine the specific metabolism pattern of an organ. The proteolytic activity of subcutaneous tissue, for example, results in a partial loss of activity of subcutaneously administrated interferon-γ compared to intravenously administrated interferon-γ.

3.4.2 Gastrointestinal Elimination

For orally administered peptides and proteins, the gastrointestinal tract is the major site of metabolism. Presystemic metabolism is the primary reason for their lack of oral bioavailability. Parenterally administered peptides and proteins, however, may also be metabolized in the intestinal mucosa following intestinal secretion. At least 20% of the degradation of endogenous albumin takes place in the gastrointestinal tract.

3.4.3 Renal Elimination

For parenterally administered and endogenous peptides and proteins, the kidneys are the major elimination organ if they are smaller than the glomerular filtration limit of ~60 kD, although the effective molecule radius is probably the limiting factor. The importance of the kidney as an elimination organ could, for example, be shown for interleukin-2, M-CSF (human macrophage colony-stimulating factor) and interferon-α.

Various renal processes contribute to the elimination of peptides and proteins (Fig. 2). For most substances, glomerular filtration is the dominant, rate-limiting step, as subsequent degradation processes are not saturable under physiologic conditions. Hence, the renal contribution to the overall elimination of peptides and proteins is reduced if the metabolic activity for these proteins is high in other body regions, and it becomes negligible in the presence of unspecific degradation throughout the body. In contrast to that, the renal contribution to total clearance approaches 100% if the metabolic activity is low in other tissues or if distribution is limited. For recombinant IL-10, for instance, elimination correlates closely with glomerular filtration rate, making dosage adjustments necessary in patients with impaired renal function.

After glomerular filtration, small linear peptides undergo intraluminal metabolism, predominantly by exopeptidases in the luminal brush border membrane of the proximal tubules. The resulting amino acids are transcellularly transported back into the systemic circulation. Larger peptides and proteins are actively reabsorbed in the proximal tubules *via* endocytosis. This cellular uptake is followed by addition of lysosomes and hydrolysis to peptide fragments and amino acids, which are returned to the systemic circulation. Therefore, only minuscule amounts of intact protein are detectable in urine. An additional renal elimination mechanism is peritubular extraction from post glomerular capillaries with subsequent intracellular metabolism, which has, for example, been described for vasopressin and calcitonin.

3.4.4 Hepatic Elimination

Apart from proteolysis and the kidneys, the liver contributes substantially to the metabolism of peptide and protein drugs. Degradation usually starts

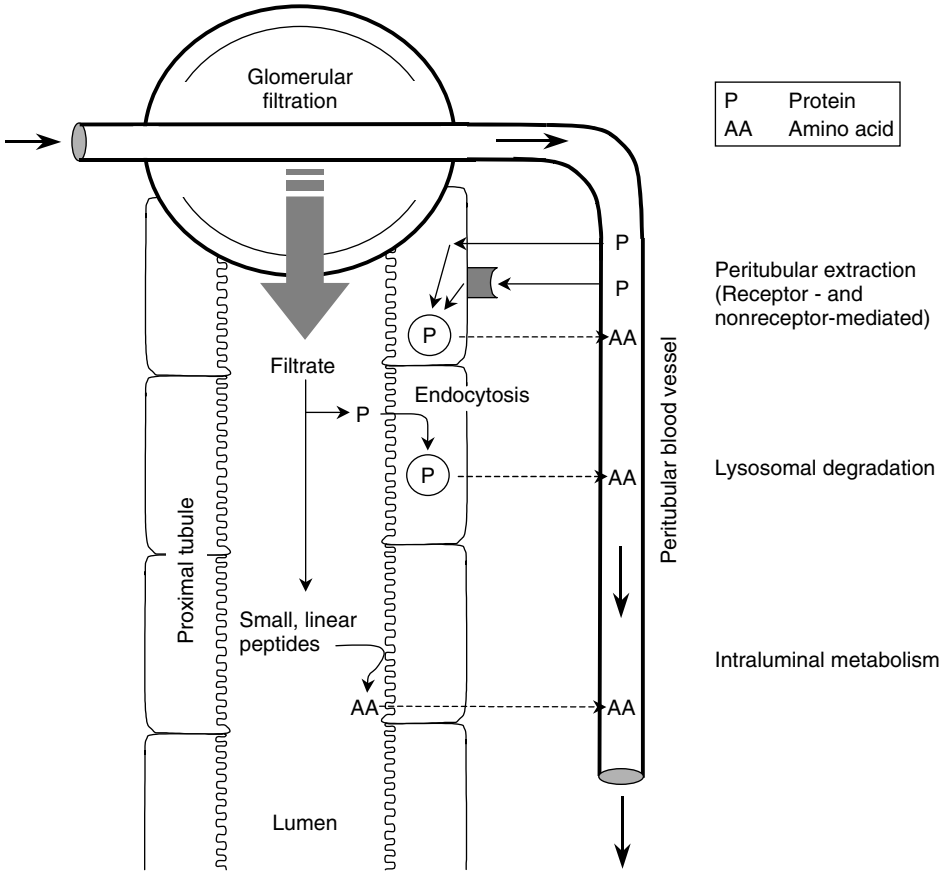

Fig. 2 Renal elimination processes of peptides and proteins: glomerular filtration, intraluminal metabolism, tubular reabsorption with intracellular lysosomal metabolism, and peritubular extraction with intracellular lysosomal metabolism.

with endopeptidases that attack in the middle part of the protein, and the resulting oligopeptides are then further degraded by exopeptidases. The ultimate metabolites of proteins, amino acids, and dipeptides are finally reutilized in the endogenous amino acid pool. The rate of hepatic metabolism is largely dependent on specific amino acid sequences in the protein.

An important first step in the hepatic metabolism of proteins and peptides is the uptake into hepatocytes. Small peptides may cross the hepatocyte membrane *via* passive diffusion if they have sufficient hydrophobicity. The uptake of larger peptides and proteins is facilitated *via* various carrier-mediated, energy-dependent transport processes. Receptor-mediated endocytosis is an additional mechanism for uptake into hepatocytes (see Sect. 3.4.5). In addition, peptides such as metkephamid can be metabolized on the surface of hepatocytes or endothelial cells.

3.4.5 **Receptor-mediated Elimination**

For conventional small-molecule drugs, receptor binding is usually negligible compared to the total amount of drug in the body, and rarely affects their PK profile. By contrast, a substantial fraction of a peptide or protein dose can be bound to receptors. This binding can lead to elimination through receptor-mediated uptake and subsequent intracellular metabolism. The endocytosis process is not limited to hepatocytes, but can occur in other cells as well, including the therapeutic target cells. Since the number of receptors is limited, their binding and the related drug uptake can usually be saturated within therapeutic concentrations. Thus, receptor–mediated elimination constitutes a major source for nonlinear PK behavior of numerous peptide and protein drugs, that is, a lack of dose proportionality.

M-CSF, for example, undergoes, besides linear renal elimination, a nonlinear elimination pathway that follows Michaelis–Menten kinetics and is linked to a receptor-mediated uptake into macrophages. At low concentrations, M-CSF follows linear PKs, while at high concentrations, nonrenal elimination pathways are saturated, resulting in nonlinear PK behavior (Fig. 3). Other examples for receptor-mediated elimination are insulin, t-PA, epidermal growth factor (EGF), ANP, and interleukin-10.

A mechanism-based, target-mediated drug distribution model was, for example, developed in order to accurately describe the nonlinear PKs of a recombinant human vascular endothelial growth factor ($rhVEGF_{165}$) in patients with coronary artery disease. Nonlinearity was caused by elimination of $rhVEGF_{165}$ by binding

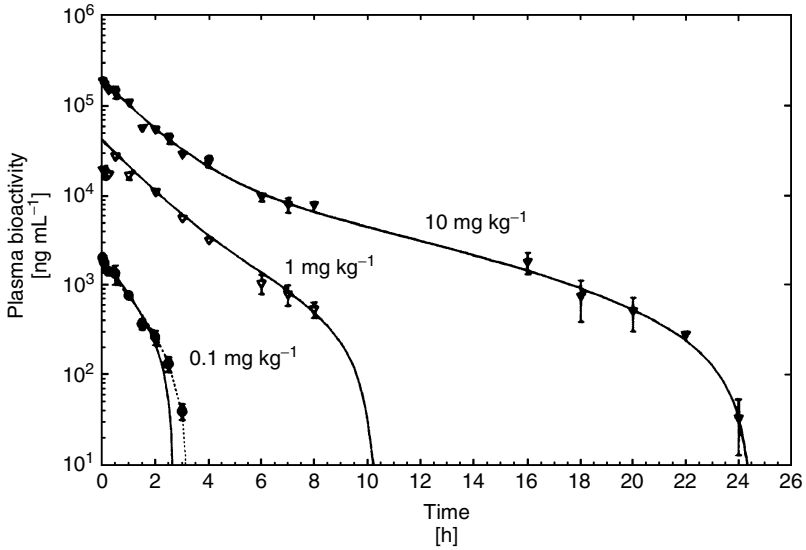

Fig. 3 Nonlinear pharmacokinetics of M-CSF, presented as measured and modeled plasma concentration–time curves (mean ± SE) after intravenous injection of 0.1 mg kg^{-1} ($n = 5$), 1.0 mg kg^{-1} ($n = 3$) and 10 mg kg^{-1} ($n = 8$) in rats (Reprinted with permission from Bauer, R.J., Gibbons, J.A., Bell, D.P., Luo, Z.P., Young, J.D. (1994) Nonlinear pharmacokinetics of recombinant human macrophage colony-stimulating factor (M-CSF) in rats, *J. Pharmacol. Exp. Ther.* **268**, 152–158).

to specific and saturable high-affinity receptors followed by internalization and degradation.

3.5 Species Specificity and Allometry

Peptides and proteins exhibit distinct species specificity with regard to structure and activity. Peptides and proteins with identical physiological function may have different amino acid sequences in different species and may have no activity or be even immunogenic if used in a different species. The extent of glycosylation is another factor of species differences, for example, for interferon-α or erythropoietin, which may alter the drug's clearance. This is of particular importance if the production of human proteins is carried out using bacterial cells.

Extrapolation of animal data to predict PK parameters by allometric scaling is an often-used tool in drug development with multiple approaches available at variable success rates. In the most frequently used approach, PK parameters between different species are related to each other *via* body weight using a power function:

$$P = a \cdot W^b \qquad (2)$$

where P is the PK parameter scaled, W is the body weight in kilograms, a is the allometric coefficient, and b is the allometric exponent. a and b are specific constants for each parameter of a compound. General tendencies for the allometric exponent are 0.75 for rate constants (i.e. clearance, elimination rate constant), 1 for volumes of distribution, and 0.25 for half-lives.

For most traditional, small-molecule drugs, allometric scaling is often imprecise, especially if hepatic metabolism is a major elimination pathway and/or if there are interspecies differences in metabolism. For peptides and proteins, however, allometric scaling has frequently proven to be much more precise and reliable, probably because of the similarity in handling peptides and proteins between different mammalian species. Clearance and volume of distribution of numerous therapeutically used proteins like somatotropin or t-PA follow a well-defined, weight-dependent physiologic relationship between lab animals and humans. This allows relatively precise quantitative predictions for toxicology and dose-ranging studies based on preclinical findings.

Figure 4 shows the allometric plots of PK parameters for the recombinant, soluble, and chimeric form of P-selectin glycoprotein ligand-1 (rPSGL-Ig), an antagonist to P-selectin for the treatment of P-selectin-mediated diseases like thrombosis, reperfusion injury, and deep vein thrombosis. Human rPSGL-Ig PK parameters could accurately be predicted on the basis of data from mouse, rat, monkey, and pig, using allometric power functions.

3.6 Immunogenicity

Because of the antigenic potential of proteins, the formation of antibodies is a frequently observed phenomenon during chronic therapy with protein drugs, especially if human proteins are used in animal studies or if animal-derived proteins are applied in human clinical studies.

Most monoclonal antibodies are murine in nature and their systemic administration can lead to the development of human antimouse immunoglobulin antibody (HAMA) response, which is in most cases directed against the constant

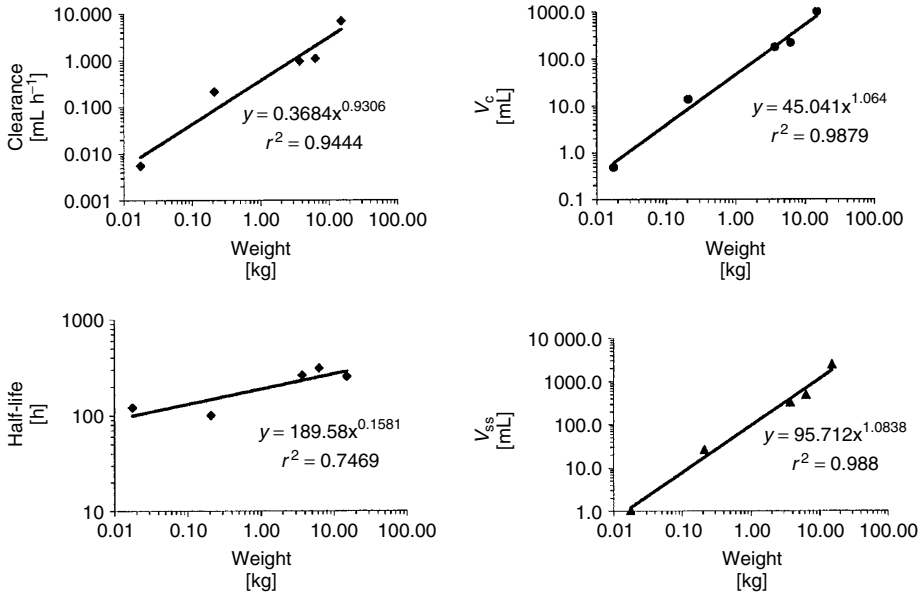

Fig. 4 Allometric plots of the pharmacokinetic parameters clearance, volume of the central compartment (V_c), volume of distribution at steady state (V_{ss}), and elimination half-life of rPSGL-Ig. Each data point within the plot represents an averaged value of the pharmacokinetic parameter with increasing weight from mouse, rat, monkey (3.74 kg), monkey (6.3 kg), and pig, respectively. The solid line is the best fit with a power function to relate pharmacokinetic parameters to body weight (Reprinted with permission from Khor, S.P., McCarthy, K., DuPont, M., Murray, K., Timony, G. (2000) Pharmacokinetics, pharmacodynamics, allometry, and dose selection of rPSGL-Ig for phase I trial, *J. Pharmacol. Exp. Ther.* **293**, 618–624).

regions of the immunoglobulin. Genetically engineered mouse–human chimeric antibodies try to minimize this immunogenicity in man by joining variable domains of the mouse to the constant regions of human immunoglobulins. The anti-EGFR (epidermal growth factor receptor) IgG monoclonal antibody cetuximab is an example of a murine–human chimeric antibody recently approved for various cancer indications.

Extravascular injection is known to stimulate antibody formation more than intravenous application, most likely due to the increased immunogenicity of protein aggregates and precipitates formed at the injection site. The presence of antibodies can obliterate the biological activity of a protein drug. In addition, protein–antibody complexation can also modify the distribution, metabolism, and excretion, that is, the PK profile, of the protein drug. Elimination can be either increased or decreased. Faster elimination of the complex occurs if the reticuloendothelial system is stimulated. Elimination is slowed down if the antibody–drug complex forms a depot for the protein drug. This effect would prolong the drug's therapeutic activity and might be beneficial if the complex formation does not decrease therapeutic activity. Furthermore, antibody binding may also interfere with bioanalytical methods like immunoassays.

4 Pharmacokinetics of Oligonucleotides

Antisense oligonucleotides hold great promise as novel therapeutic agents designed to specifically and selectively inhibit the production of disease-related products, with fomivirsen being the first approved antisense oligonucleotide drug product. So far, a significant body of preclinical and human PK data is available only for phosphothioate oligonucleotides (PONs).

Oral bioavailability is generally very low, ranging from 1 to 3%. Ongoing studies, however, indicate that oral bioavailability can be increased by the appropriate release of drug and permeability-enhancing excipients. PONs have also been administered *via* subcutaneous, intradermal, and pulmonary application routes.

After intravenous administration, PONs generally follow two-compartment characteristics and are rapidly cleared from plasma, predominantly *via* distribution processes with a half-life of 0.5 to 1 h depending on the dose. The ICAM-1 inhibitor alicaforsen, for example, has a distribution half-life of 1.0 to 1.2 h in humans. Plasma PKs are nonlinear, with a more than proportional increase in area-under-the-curve (AUC) with dose. This is most probably due to saturation of tissue uptake. Figure 5, for example, shows the disproportional increase in systemic exposure after escalating doses of the HIV-inhibitor trecovirsen. The plasma PKs of various ONs are generally independent of their sequence and chemistry as plasma clearance is primarily determined by distribution processes.

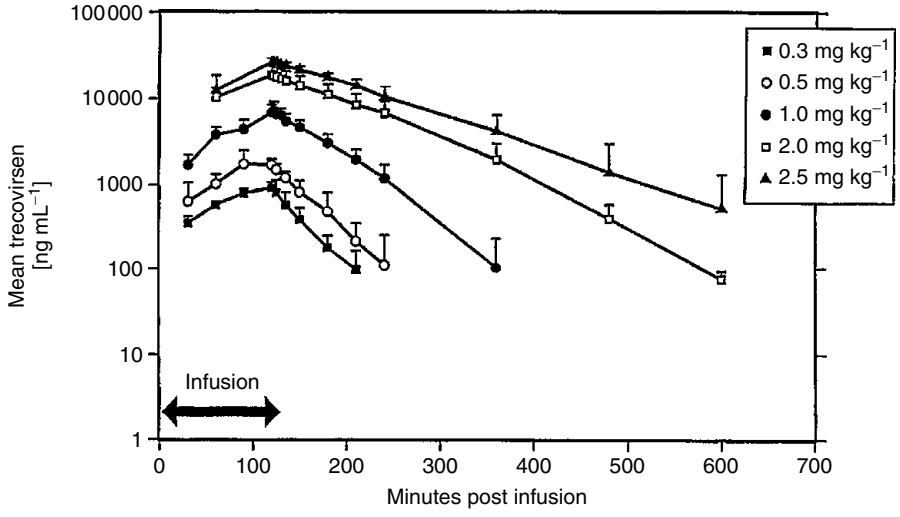

Fig. 5 Plasma concentration-time course of the antisense oligonucleotide trecovirsen in HIV-positive subjects, indicating a disproportional increase in systemic exposure after escalating doses. Trecovirsen was administered by 2-h intravenous administration to groups of six subjects (12 subjects for the 1.0 mg kg^{-1} dose group). (Reprinted with permission from Sereni, D., Tubiana, R., Lascoux, C., Katlama, C., Taulera, O., Bourque, A., Cohen, A., Dvorchik, B., Martin, R.R., Tournerie, C., Gouyette, A., Schechter, P.J. (1999) Pharmacokinetics and tolerability of intravenous trecovirsen (GEM 91), an antisense phosphorothioate oligonucleotide, in HIV-positive subjects, *J. Clin. Pharmacol.* **39**, 47–54).

After intravenous administration, PONs are detected in nearly all tissues and organs except brain and testes, suggesting significant transport barriers in these tissues. The extent of tissue uptake is dependent on the dose amount as well as dose rate. A major accumulation of PON occurs in liver and kidneys, and to a lesser extent in spleen, bone marrow, and lymph nodes, which seems to be independent of PON sequence. Chemical modification of the phosphothioate backbone structure may, however, alter protein binding and organ distribution. The mechanisms for uptake into target cells have not been fully elucidated yet, but these processes are energy-, temperature-, and time-dependent, and probably include pinocytosis and podocytosis.

PONs are cleared from tissues by nuclease-mediated metabolism, with half-lives that vary between 20 and 120 h, depending on the organ or tissue. Successive removal of bases from the 3′-end is the major metabolic pathway in plasma, while both 3′ and 5′ exonuclease excision may occur in tissues. Exonuclease metabolism in plasma and tissues is rapid, with 30 to 40% of PON having at least one nucleotide removed after 5 min in plasma. Endonuclease-mediated degradation of PONs is generally not observed.

PONs are highly bound to plasma proteins that protect them from renal filtration. Plasma protein binding of ISIS2503, for example, ranged from 95 to 97% in rats and monkeys, but was saturable at high concentrations. Urinary excretion is a major route of excretion for PONs, regardless of sequence or chemical structure, with the majority being shorter-length metabolites rather than unchanged parent drug. Urinary excretion is nonlinear, with a greater fraction excreted at higher doses. Potential mechanisms include saturation of plasma protein binding as well as tubular reuptake mechanisms. Only a minor fraction of the dose is excreted into feces, although enterohepatic recirculation has been suggested.

ISIS 104838 is a tumor necrosis factor-α (TNF-α) inhibiting second-generation ON containing five 2′-O-(2-methoxyethyl) modified (2′-MOE) nucleosides at the 3′- and 5′-terminus, respectively. The PK pattern for this second-generation PON was similar to first-generation PONs, except for a less pronounced nonlinearity in systemic exposure and a substantially prolonged terminal half-life of 27 ± 3.8 days, most probably due to the complete blockade of exonuclease digestion by the MOE modification.

5 Pharmacokinetics of DNA

In comparison to peptides, proteins, and oligonucleotides, much less is known about the PKs of recombinant plasmid DNA used like a ''drug'' in the novel treatment approach of gene therapy.

The *in vivo* disposition of plasmid DNA and its complexes depends largely on its physicochemical characteristics, a strong negative charge, and high molecular weight. After intravenous administration in rats, pDNA is detected in all major organs including lungs, liver, kidney, and spleen. Low-level detection in the brain is most likely an artifact from residual blood, given that pDNA is unlikely to cross the blood-brain barrier.

After intravenous administration in mice, pDNA is rapidly eliminated from the plasma due to extensive uptake into the liver as well as rapid degradation by nucleases, with hepatic uptake clearance approaching liver plasma

flow. pDNA is preferentially taken up by liver nonparenchymal cells, such as Kupffer and endothelial cells *via* receptor-mediated processes.

Analysis of the functional forms of pDNA in rats revealed that supercoiled pDNA rapidly disappears from plasma with a half-life of 0.15 min. Approximately 60% of supercoiled pDNA is degraded to open circular pDNA, which is subsequently almost completely converted to linear pDNA. The conversion of open circular to linear pDNA followed Michaelis–Menten kinetics, while linear pDNA was removed with a half-life of 2.1 min. The slower elimination of open circular and linear pDNA as compared to supercoiled pDNA was suggested to be related to a stronger interaction with plasma macromolecules that might offer some protection from plasma nuclease degradation.

6 Exposure/response Correlations for Biotech Drugs

Since biotech drugs are usually highly potent compounds with steep dose–effect curve, a careful characterization of the dose–concentration–effect relationship should receive particular emphasis during the preclinical and clinical drug development process. Integrated PK/PD modeling approaches have widely been applied for the characterization of biotech drugs. PK/PD modeling not only allows for a continuous description of the time course of effect as a function of the dosing regime and comprehensive summary of available data but also enables testing of competing hypotheses regarding processes altered by the drug, allows to make predictions of drug effects under new conditions, and facilitates the estimation of inaccessible system variables.

The application of PK/PD modeling is beneficial in all phases of preclinical and clinical drug development, with a focus on dosage optimization and identification of covariates that are causal for intra- and interindividual differences in drug response and/or toxicity. It has recently been further endorsed by the publication of the Exposure–Response Guidance document by the US Food and Drug Administration. Mechanism-based PK/PD modeling, which appreciates the physiological events involved in the elaboration of the observed effect, has been promoted as a superior modeling approach when compared to empirical modeling, especially because it not only describes observations but also offers some insight into the underlying biological processes involved and thus provides flexibility in extrapolating the model to other clinical situations. Since the molecular mechanism of action of biotech drugs is generally well understood, it is often straightforward to transform this available knowledge into a mechanism-based PK/PD modeling approach that appropriately characterizes the real physiological process leading to the drug's therapeutic effect.

In the following, the application of the three most common PK/PD modeling classes, direct-link models, indirect-link models, and indirect-response models, will be discussed in more detail. In addition, extensions of these concepts and more complex approaches will be introduced in illustrative examples. However, it should be mentioned that PK/PD models for biotech drugs are not limited only to continuous responses as shown in the following but are also used for binary or graded responses. A logistic PK/PD modeling approach was, for example, used to

link cumulative AUC of the anti-TNF-α protein etanercept with the American College of Rheumatology response criterion of 20% improvement (ARC20) in patients with rheumatoid arthritis.

6.1 Direct Link PK/PD Models

While drug concentrations are usually analytically quantified in plasma, serum, or blood, the magnitude of the observed response is determined by the concentration of the drug at its effect site, the site of action in the target tissue. The relationship between the drug concentration in plasma and at the effect site may either be constant or undergo time-dependent changes. If equilibrium between both concentrations is rapidly achieved or the site of action is within plasma, serum, or blood, there is practically a constant relationship between both concentrations with no temporal delay between plasma and effect site. In this case, measured concentrations can directly serve as input for a PD model. The most frequently used direct-link PD model is the sigmoid E_{max}-Model:

$$E = \frac{E_{max} \cdot C^n}{EC_{50}^n + C^n} \qquad (3)$$

with E_{max} as maximum achievable effect, C as drug concentration at the effect site, and EC_{50} the concentration of the drug that produces half of the maximum effect. The Hill coefficient n is a shape factor that allows for an improved fit of the relationship to the observed data. Thus, a direct-link model directly connects measured concentration to the observed effect without any temporal delay.

A. Racine-Poon et al. provided an example for a direct-link model by relating the serum concentration of the antihuman immunoglobulin E (IgE) antibody CGP 51901 for the treatment of seasonal allergic rhinitis to the reduction of free IgE *via* an inhibitory E_{max}-model. Similarly, a direct-link model was applied to assess the effect of recombinant interleukin-10 on the *ex vivo* release of the proinflammatory cytokines TNF-α and interleukin-1β (IL-1β) in LPS-stimulated leukocytes.

6.2 Indirect Link PK/PD Models

The concentration–effect relationship of many biotech drugs, however, cannot be described by direct-link PK/PD models, but is characterized by a temporal dissociation between the time courses of plasma concentration and effect. In this case, concentration maxima would occur before effect maxima, effect intensity would increase despite decreasing plasma concentrations and would persist beyond the time when drug concentrations in plasma are no longer determinable. The relationship between measured concentration and observed effect follows a counterclockwise hysteresis loop. This phenomenon can be caused either by an indirect-response mechanism (see Sect. 6.3) or by a distributional delay between the concentrations in plasma and at the effect site. The latter can conceptually be described by an effect-compartment model, which attaches a hypothetical effect-compartment to a PK compartment model. The effect-compartment does not account for mass balance and only defines the changes in concentration at the effect site *via* the time course of the effect itself.

An effect-compartment approach was, for example, applied to quantify the reduction in mean arterial blood pressure by the antiadrenergic peptoid CHIR 2279. The same concept was used by Pihoker

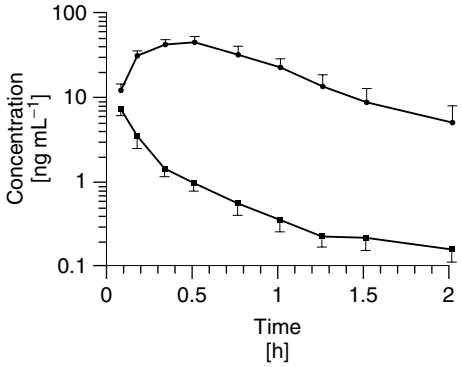

Fig. 6 Serum concentration profiles (mean ± SD) of GHRP-2 (growth hormone–releasing peptid-2; ■) and endogenous somatotropin (●) after intravenous administration of 1μ g kg^{-1} GHRP-2 in prepubertal children ($n = 10$). (Reprinted with permission from Pihoker, C., Kearns, G.L., French, D., Bowers, C.Y. (1998) Pharmacokinetics and pharmacodynamics of growth hormone-releasing peptide-2: a phase I study in children, *J. Clin. Endocrinol. Metab.* **83**, 1168–1172. Copyright 1998, The Endocrine Society).

et al. to characterize the relationship between the serum concentration of the somatotropin-releasing peptide GHRP-2 and somatotropin (Fig. 6).

6.3 Indirect-response PK/PD Models

The effect of most biotech drugs, however, is not mediated *via* a direct interaction between drug concentration and response systems, but frequently involves several transduction processes that include, at their rate-limiting step, the stimulation or inhibition of a physiologic process, for example, the synthesis or degradation of a molecular response mediator like a hormone or cytokine. In these cases, mechanism-based indirect-response models should be used that appreciate the underlying physiological process involved in mediating the observed effect. Indirect-response models generally describe the effect on a representative response parameter *via* the dynamic equilibrium between increase or synthesis and decrease or degradation of the response, with the former being a zero-order and the latter a first-order process. Each of these processes can be stimulated or inhibited in four derived basic model variants.

Two variants of the indirect-response models, stimulation of synthesis and of degradation processes were, for example, used in a recent study for modeling the effect of recombinant erythropoietin on the two response parameters, free ferritin (*Fr*) concentration and soluble transferrin receptor (*Tfr*) concentration. While erythropoietin reduces *Fr*, it increases *Tfr* (Fig. 7). The temporal change in both response variables can be described by the following equations:

$$\frac{dFr}{dt} = k_{in,F} - k_{out,F} \cdot \left(1 + \frac{E_{max} \cdot C_m^n}{EC_{50}^n + C_m^n}\right) \cdot Fr$$

$$\frac{dTfr}{dt} = k_{in,T} \cdot \left(1 + \frac{E_{max} \cdot C_m^n}{EC_{50}^n + C_m^n}\right) - k_{out,T} \cdot Tfr \quad (4)$$

with k_{in} as endogenous formation rate of *Fr* and *Tfr*, and k_{out} as first-order degradation rate constant, respectively. C_m is the erythropoietin concentration that was additionally modulated *via* a transduction process with 50-h delay.

Similarly, a modified indirect-response model was used to relate the concentration of the humanized antifactor IX antibody

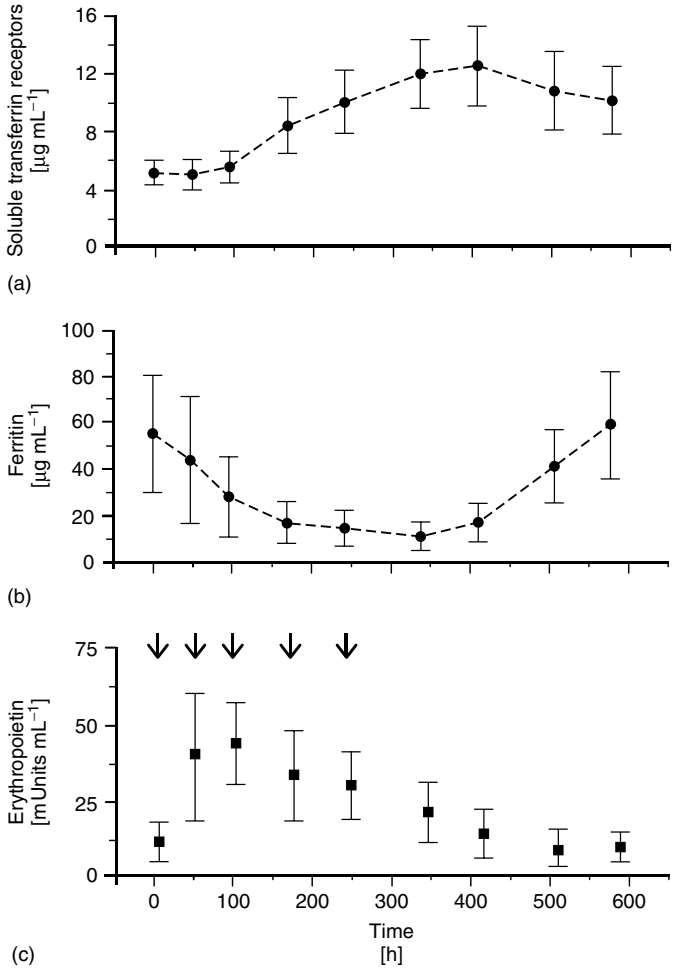

Fig. 7 Serum concentration–time course (mean ± SD) of erythropoietin (c) and its effect on the concentrations of free ferritin (b) and soluble transferrin receptor (a) after repeated subcutaneous administration of 200 U kg^{-1} recombinant erythropoietin in athletes ($n = 18$) (Reprinted with permission from Bressolle, F., Audran, M., Gareau, R., Pham, T.N., Gomeni, R. (1997) Comparison of a direct and indirect population pharmacodynamic model: application to recombinant human erythropoietin in athletes, *J. Pharmacokinet. Biopharm.* **25**, 263–275).

SB249417 to factor IX activity in Cynomolgus monkeys as well as humans. The drug effect in this model was introduced by interrupting the natural degradation of Factor IX by sequestration of factor IX by the antibody.

Indirect-response models were also used for the effect of somatotropin on endogenous IGF-1 concentration, as well as the immune suppressive activity of the monoclonal antibody mAb 5c8.

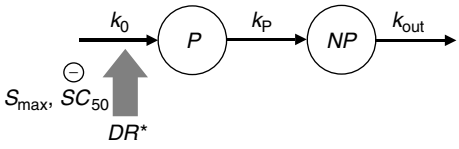

Fig. 8 Schematic representation of an indirect-response model with precursor pool used to describe the effect of interferon-β 1a (represented by its internalized drug-receptor complex DR^*) on endogenous neopterin concentrations (NP) *via* stimulation of the synthesis of its precursor neopterin triphosphate (P). See text for discussion of the details (Modified from Mager, D.E., Neuteboom, B., Efthymiopoulos, C., Munafo, A., Jusko, W.J. (2003a) Receptor-mediated pharmacokinetics and pharmacodynamics of interferon-β 1a following intravenous and subcutaneous dosing in monkeys, *J. Pharmacol. Exp. Ther.* **26**, 26.

Although physiologically related mechanism-based modeling should be preferred, an indirect-response–based temporal dissociation between time course of concentration and effect can also be modeled with the effect-compartment approach. The effect of the growth hormone–releasing peptid (GHRP) ipamorelin on somatotropin, for example, was described by a physiologically based indirect-response model, while the already mentioned GHRP-2 effect on somatotropin was characterized with an effect-compartment approach. Similarly, effect-compartment as well as indirect-response models were applied for characterizing the effect of insulin on blood glucose levels. A recent comparative study, however, suggests that a mechanism-based indirect-response model is a more appropriate approach for modeling the PK/PD of insulin.

6.4 Precursor Pool PK/PD Models

An extension of indirect-response models are precursor pool-dependent indirect-response models that include the liberation of an endogenous compound from a storage pool. These models possess the unique ability to characterize both tolerance and rebound phenomena. Such a model was, for example, used to describe the effect of interferon-β1a on neopterin, an endogenous marker for cell-mediated immunity in humans and monkeys (Fig. 8). The primary elimination mechanism of interferon-β1a was modeled as receptor-mediated endocytosis, and the PD model was driven by the amount of internalized drug-receptor complex DR^*:

$$\frac{dP}{dt} = k_0 \cdot \left(1 + \frac{S_{max} \cdot DR^*}{SC_{50} + DR^*}\right) - k_p \cdot P \tag{5}$$

where P is the concentration of neopterin precursor (neopterin triphosphate), k_0 is the zero-order production rate of precursor P, and k_p is the first-order rate constant characterizing the conversion of precursor P to neopterin. The amount of internalized DR^* stimulates precursor production *via* a stimulation function governed by the maximum effect parameter S_{max} and a sensitivity parameter SC_{50}, the concentration that results in half of S_{max}. The rate of change in neopterin concentration NP is then defined by the following expression:

$$\frac{dNP}{dt} = k_p \cdot P - k_{out} \cdot NP \tag{6}$$

with k_{out} as the first-order elimination rate constant of NP in the body.

6.5 Complex PK/PD Models

Since the effect of most biotech drugs is mediated *via* complex regulatory physiologic processes including feedback mechanisms and/or tolerance phenomena, some

PK/PD models that have been described for biotech drugs are much more sophisticated than the four classes of models previously discussed. One example of such a complex modeling approach has been developed for the therapeutic effects of the LH-RH antagonist cetrorelix.

Cetrorelix is used for the prevention of premature ovulation in women undergoing controlled ovarian stimulation in *in vitro* fertilization protocols. LH-RH antagonists suppress the LH levels and delay the occurrence of the preovulatory LH surge, and this delay is thought to be responsible for postponing ovulation. The suppression of LH was modeled in the PK/PD approach with an indirect-response model approach directly linked to cetrorelix plasma concentrations (Fig. 9). The shift in LH surge was linked to cetrorelix concentration, with a simple E_{max}-function *via* a hypothetical effect-compartment to account for a delay in response *via* complex signal transduction steps of unknown mechanism of action. The combined effect of LH suppression and delaying the LH surge was described by the following relationship:

$$\frac{dLH}{dt} = k_0 \cdot \left(1 - \frac{C}{IC_{50} + C}\right) \cdot \left(1 + \frac{SA}{\left(\frac{t - \left(T_0 + \frac{E_{max} \cdot C_e}{EC_{50} + C_e}\right)}{SW}\right)^N + 1}\right) - k_e \cdot LH \tag{7}$$

where LH is the LH concentration, k_0 and k_e are the zero-order production rate and first-order elimination rate constants for LH at baseline, C and C_e are the cetrorelix concentrations in plasma and a hypothetical effect-compartment respectively, SA is the LH surge amplitude, t is time, T_0 is the time at which the peak occurs under baseline conditions, SW is the width of the peak in time units, IC_{50} is the cetrorelix

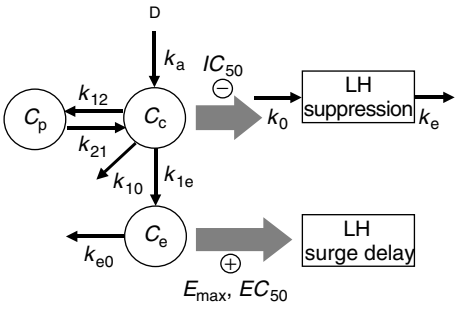

Fig. 9 PK/PD model for the LH suppression and the delay in LH surge following administration of a cetrorelix dose (D). C_C, C_P, and C_e: Concentration of drug in central, peripheral, and effect compartments, respectively; k_a, k_{12}, k_{21}, k_{10}, k_{1e}, k_{e0}: pharmacokinetic first-order rate constants. See text for discussion of the details (Modified from Nagaraja, N.V., Pechstein, B., Erb, K., Klipping, C., Hermann, R., Locher, M., Derendorf, H. (2003) Pharmacokinetic/pharmacodynamic modeling of luteinizing hormone (LH) suppression and LH surge delay by cetrorelix after single and multiple doses in healthy premenopausal women, *J. Clin. Pharmacol.* **43**, 243–251).

concentration that suppresses LH levels by 50%, E_{max} is the maximum delay in LH surge, and EC_{50} is the cetrorelix concentration that produces half of E_{max}. N describes the slope of the surge peak and is an even number. Baseline data analysis indicated that N and SW were best fixed at values of 4 and 24 h, respectively.

Figure 10 shows the application of this PK/PD model to characterize the LH

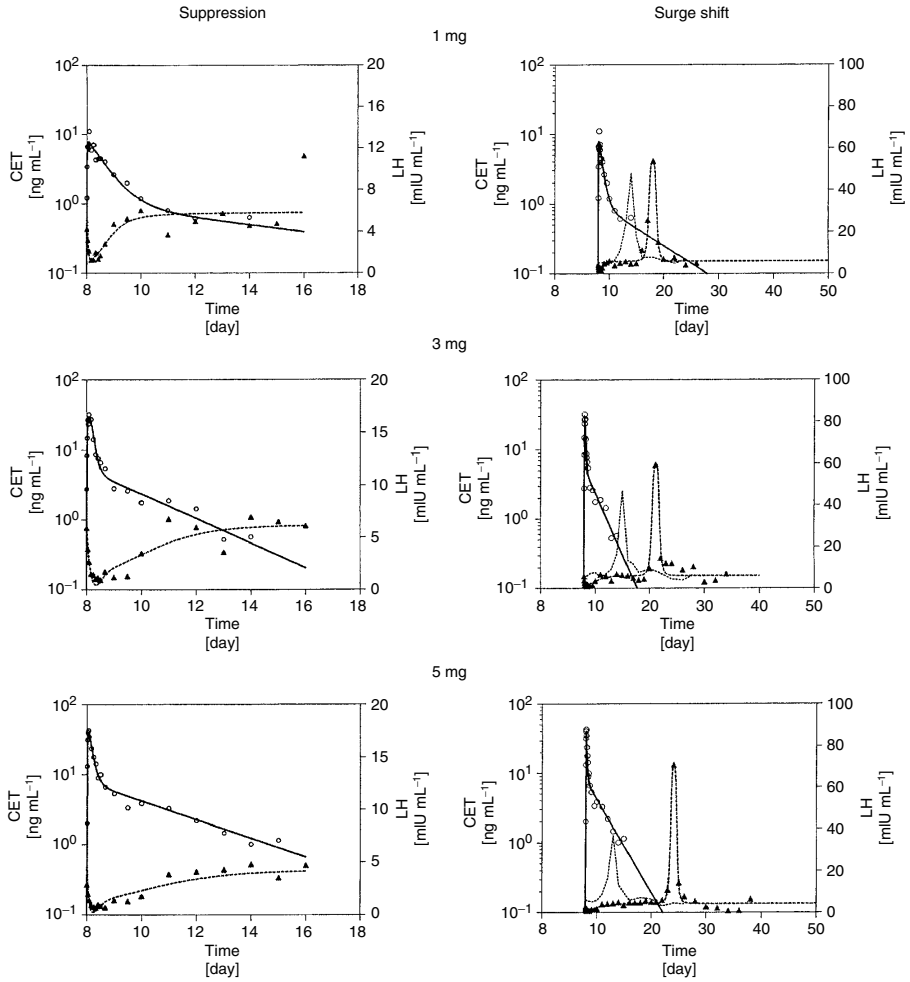

Fig. 10 PK and PD relationship between cetrorelix (O) and LH concentrations (▲) after single doses of 1, 3, and 5 mg cetrorelix in representative subjects. Left panel: LH suppression. Right panel: LH suppression and LH surge profiles. The thick solid line represents the model-fitted cetrorelix concentration; the broken line the model-fitted LH concentration; and the thin dotted line the pretreatment LH profile (not fitted) (Reprinted with permission from Nagaraja, N.V., Pechstein, B., Erb, K., Klipping, C., Hermann, R., Niebch, G., Derendorf, H. (2000) Pharmacokinetic and pharmacodynamic modeling of cetrorelix, an LH-RH antagonist, after subcutaneous administration in healthy premenopausal women, *Clin. Pharmacol. Ther.* **68**, 617–625).

suppression and LH surge delay after subcutaneous administration of cetrorelix to groups of 12 women at different dose levels. The analysis revealed a marked dose–response relationship for the LH surge, and thus predictability of drug response to cetrorelix.

An even more complex, mechanism-based modeling approach including tolerance phenomena was used for the effect of antide, an LH-RH antagonist, on the endogenous regulatory mechanisms and plasma concentrations of LH and testosterone.

7 Summary

In general, biotech drugs conform to the same PK and PD principles as traditional, small-molecule drugs. On the basis of their similarity to endogenous compounds or nutrients, however, numerous caveats and pitfalls related to bioanalytics and PKs have to be considered and addressed during the development process, and this may require additional resources. Furthermore, PDs is frequently complicated owing to close interaction with endogenous substances and specific feedback mechanisms.

Biotech drugs, including peptides, proteins and antibodies, oligonucleotides, and DNA, are projected to cover a substantial market share in the health care systems of the future. It will be crucial for their widespread application in pharmacotherapy, however, that their respective drug development programs are successfully completed in a rapid, cost-efficient, and goal-oriented manner. A more widespread application of PK and PD concepts including exposure–response correlations has repeatedly been promoted by industry, academia, and regulatory authorities for all preclinical and clinical phases of drug development and is believed to result in a scientifically driven, evidence-based, more focused and accelerated drug product development process. Thus, PK/PD concepts are likely to continue and expand their role as a decisive factor in the successful development of biotechnologically derived drug products in the future.

Keywords

Aptamer
A short single-stranded nucleic acid selected from combinatorial libraries to bind specific target molecules through a protocol termed SELEX (Systematic Evolution of Ligands by EXponential enrichment).

Pharmacokinetics
The action and metabolism of pharmaceuticals (drugs) in the body, including the processes of absorption, biotransformation, distribution to tissues, and duration of action and elimination.

PNA (Peptide Nucleic Acid)
A nucleic acid analog in which the entire phosphate sugar backbone has been replaced by an uncharged polyamide backbone with the side groups, purine and pyrimidine bases, found in biological nucleic acids.

Ribozyme
Catalytic RNA, capable of cleaving target RNA of specific sequence.

RNA Drug
Different types of RNA molecules (aptamers, ribozyme, siRNA, and so on) that can be used for therapeutical and/or diagnostic purposes.

RNA interference (RNAi)
A novel mechanism induced by double-stranded RNA that leads to posttranscriptional gene silencing by sequence-specific degradation or translational inhibition of specific transcripts.

Spiegelmer
Biostable aptamers that are synthesized from L-nucleotides (the mirror image of natural nucleotides), and, therefore, cannot be degraded by naturally occurring nucleases.

In the living cell, the RNA is an important intermediate of genetic information transfer between DNA and protein. RNA is a single-stranded, flexible, and versatile biopolymer that incorporates many pharmacologically desirable traits of DNA and protein without some of their disadvantages. It is water soluble and nontoxic, produced by chemical synthesis as well as recombinant cloning, faithfully replicates the parental DNA sequence, can be converted to DNA or protein, possesses enzymatic self-cleaving activity, and makes specific RNA–RNA, RNA – DNA, and RNA–protein interactions. The biologically remarkable forms and functions of RNA, such as antisense RNA, ribozymes, RNA decoys, aptamers, and RNA interference, are rooted in this fundamentally unique combination of biochemical traits of the RNA. It is only recently that some of these properties of RNA have been exploited to interfere with or repair dysfunctional or harmful nucleic acids or proteins and to induce therapeutic gene products in a variety of pathological syndromes or infectious diseases. First and second generations of RNA drugs have indeed produced promising results, thus raising new hopes in bringing RNA therapeutics from the bench to the bedside. In this chapter, we first describe the basic features and discoveries of RNA that are relevant to its clinical usage, and then chronicle the emerging clinical applications of RNA.

1
Clinically Relevant Features of RNA and its Metabolism

1.1
RNA in Central Dogma

The core of the Central Dogma of molecular biology (Fig. 1) charts the genetic information flow in all living cells: DNA makes RNA and RNA makes protein. DNA is copied into RNA in ''transcription,'' and the messenger RNA (mRNA) is deciphered to protein in ''translation.'' To this is added the fact that DNA and RNA genomes are duplicated in ''replication,'' and, in retroviruses, the viral RNA genome can be copied in the ''retro'' (hence the name of these viruses) or ''reverse'' direction to produce DNA in a process aptly called ''reverse transcription.'' DNA replication is catalyzed by DNA polymerase and transcription by RNA polymerase (RNAP). The enzyme that copies RNA into RNA is sometimes called ''replicase'' or ''transcriptase'' (as the name ''RNA polymerase'' has already been taken by its DNA-dependent counterpart). In this chapter, however, we will follow the recent trend to call it RdRP (RNA-dependent RNA polymerase). Lastly, the reverse transcriptase (RT) catalyzes the conversion of RNA to DNA. Relevant aspects of the Central Dogma are detailed below.

DNA, the stored but otherwise useless genetic information in all cells, is double-stranded and, in comparison to RNA and protein, is relatively rigid and inflexible. Practically all naturally occurring DNA, except the very small ones (such as plasmids), are intimately complexed with proteins (such as histones in mammalian cells) to produce the chromosomes. The principal types of RNA transcribed from the DNA in a cell are listed in Table 1. Each class of RNA is produced by one of three

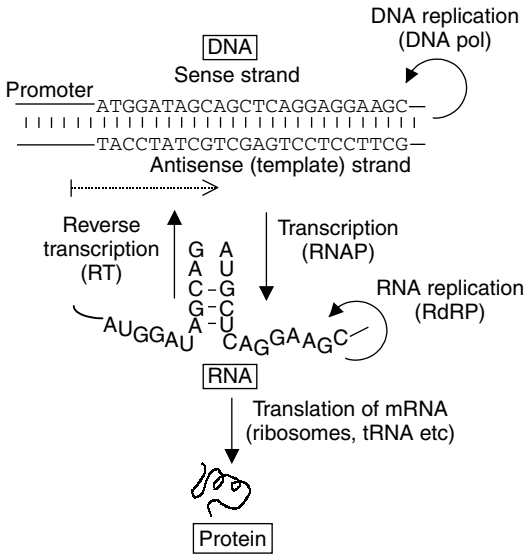

Fig. 1 The Central Dogma of molecular biology (Sect. 1.1). This Figure is not meant to serve as a comprehensive diagram of all aspect of replication, transcription, and translation, but only to provide minimal relevant information needed to understand the rest of the chapter. RNA splicing is omitted for simplicity, but is detailed in Sect. 1.4. The mRNA is shown with its 5′ cap structure and the 3′ poly(A) tail is omitted. An oversimplified RNA hairpin is shown. Nucleotides are paired by hydrogen bonds, indicated by small lines. The most important feature to note is that the RNA is located between DNA and protein, form local base pairs that resemble DNA, and at the same time folds and bends like proteins.

kinds of RNAP, often with the assistance of transcription factors, many of which are in turn regulated by physiological signals. The messenger RNA (mRNA) is the only kind of RNA that is translated into protein; hence its name as the messenger of genetic information. The majority of mammalian mRNAs are produced as pre-mRNAs containing ''exons'' and ''introns''; RNA splicing, described in Sect. 1.4, removes the introns and joins the exons to produce the processed mRNA ready for translation. By virtue of its protein-coding nature, the mRNA has evolved to be more labile and subject to a relatively greater temporal, developmental, and tissue-specific regulation than the rRNA and tRNA. While replication and transcription of DNA genomes occur in the nucleus, translation is cytoplasmic. Replication and transcription of RNA genomes, such as those of viruses, is also a cytoplasmic event, with few exceptions.

RNAP initiates transcription at a specific sequence on the DNA, known as a *promoter*, and copies only one strand of the DNA. There are various conventions to describe the two nucleic acid strands, depending on the focus of the discussion. We prefer to call the RNA the ''sense'' strand because this is the first step in the Central Dogma where a molecule that ''makes sense'' (to the translational machinery) is produced from the information encrypted in the DNA. The complementary strand of the DNA is, therefore, ''antisense'' (Fig. 1). In other words, RNAP copies the antisense strand of the DNA as template to produce the RNA. To rephrase, the RNA sequence is identical to the sense strand of the DNA (except for the T-to-U change) and complementary to the antisense strand. In describing viral RNA genomes, virologists often follow another nomenclature whereby the mRNA-sense RNA is referred to as the ''positive'' or ''plus'' strand and its complementary RNA is called ''negative'' or ''minus'' strand. As most cellular functions – structural as well as enzymatic – are performed by proteins, the overwhelming majority of conventional drugs directly target proteins. In

contrast, the majority of the emerging RNA drugs target the mRNAs that encode the proteins, and thus work at a higher level in the Central Dogma.

Translation, the last step in Central Dogma, is a far more complex process requiring the participation of ribosomes, transfer RNA, and a slew of translational factors, and, thus, there is no such single entity as ''RNA-dependent protein polymerase''! Protein is also the ultimate, dead-end product of Central Dogma, and, thus, cannot be reverse-translated. Lastly, proteins do not replicate. Note that RNA is the intermediate between the DNA and the protein, and shares features of both. In short, it has the nucleic acid property of DNA and the flexibility of protein. The following section elaborates this further.

1.2 Transcription and Replication of RNA Genomes

RNA genomes in nature are found nearly exclusively in RNA viruses that comprise a large group of pathogens that infect practically all species including human. Viral RNA genomes can be linear or circular, single or double-stranded, segmented or nonsegmented, and the single-stranded genomes can be positive or negative, sense or even ambisense (a mixture of the two). They can vary in size from a little over a hundred nucleotides (as in hepatitis delta virus and plant viroids) to around 30 000 nucleotides (as in coronoviruses that cause the severe acute respiratory syndrome, or SARS). Viruses, by definition, are obligatory parasites, and must infect host cells in order to multiply. Owing to their small size, viral genomes lack the capacity to code for the highly complex translation machinery (Fig. 1); therefore, all viruses must utilize the translational apparatus of the host. Animal cells, in general, and human cells, in particular, lack any enzymatic activity that can copy RNA templates, thus compelling all RNA viruses to encode such activities of their own. While the retroviral RNA genomes encode RT that copies the genomic RNA into complementary DNA (cDNA) to be integrated into the host chromosomal DNA, the nonretroviral RNA genomes encode RdRP that transcribes and replicates the genome exclusively in the cytoplasm. The functional viral RdRP is usually a multisubunit complex consisting of a large polymerase subunit and one or more accessory subunits. The RNA genome of positive-strand RNA viruses is essentially a sense-strand mRNA that is translated immediately after infection. The antisense genome of negative-strand RNA viruses, in contrast, must first be transcribed by the associated RdRP activity to produce mRNAs that are then translated to produce new viral proteins. Many RNA genomes, especially the negative-strand ones, are tightly wrapped by the nucleocapsid protein (N), producing the N-RNA nucleoprotein complex, which is the biological template for the RdRP. The mRNAs, in contrast, are naked. Thus, the genomic RNA is resistant to various onslaughts including prospective drugs, while the mRNA is a therapeutic target.

In contrast to the DNA genomes, RNA genomes are also highly mutable, mainly because the RdRP lacks a proofreading activity and thus is highly error prone. As a result, even the purest, clonally purified RNA virus preparation may contain a mixed population of genomes of various sequences, leading to the concept of ''quasi-species.'' This has two important implications. First, it allows the RNA virus to mutate quickly and produce ''best-fit'' mutants in a rapidly changing environment, thus enhancing its chances

of survival. By the same token, however, it also creates major hurdles in designing vaccines and other antiviral strategies against RNA viruses. Indeed, in recurring RNA viral epidemics, such as the annual episodes of human flu (caused by influenza virus), fresh vaccines are made against the new strain as the antigenic makeup of the new virus may be sufficiently different from those of the previous years, thus making the past vaccines ineffective.

1.3 Noncanonical Base Pairs in RNA

Although RNA is described as single-stranded in comparison to DNA, in reality more than half the nucleotides in the typical RNA participate in base pairing. Several motifs with various combinations of double-stranded helix, bulge, and loop are commonly found in RNA secondary structures. In small viral RNA genomes, such as viroids, virusoids, satellite RNA, and human hepatitis delta virus RNA, essentially all the bases are paired such that the RNA is practically all double-stranded and highly folded. While the Watson-Crick A:T and G:C base pairs are universal in all DNA, RNAs may contain many modified bases in addition to the standard A, C, G, and U, and the flexibility of the RNA chain allows various noncanonical base pairs as well. The most prevalent noncanonical RNA base pairs with the standard bases are GU, GA, and AC. The tRNAs often contain the modified base inosine (I), created posttranscriptionally, in the first wobble position of the anticodon; as I can pair with A, C, or U, this allows more promiscuous codon–anticodon pairing, such that fewer different tRNAs are required. As discussed later, such modified bases and alternate pairing rules may be used in designing better RNA drugs.

1.4 RNA Splicing

Typical mammalian genes are organized on the DNA in exon–intron structure, with an average of about nine exons per gene. Transcription of the DNA produces pre-mRNA, from which the introns are removed in a process called *splicing*. The process is catalyzed by a large ribonucleoprotein complex, called *spliceosome*, containing various RNA of the snRNA family (Table 1) and multiple proteins. The spliceosome recognizes sequence features of the intron–exon boundaries (splice junctions) and performs the actual cutting and joining of the RNA segments. This section will summarize the fundamental principles of how alternate splicing can be regulated by an RNA drug, and specific splice variants or faulty RNA can be destroyed or repaired by catalytic RNA drugs.

1.4.1 Alternate RNA Splicing: Regulation by Antisense RNA

Alternative splicing occurs when the introns of a particular pre-mRNA are spliced in more than one way, generating multiple mature mRNA species – and hence multiple proteins – from a single gene (Fig. 2). More than half of all human gene transcripts are estimated to undergo alternate splicing, yielding an enormous variety of mRNAs out of a relatively small repertoire of genes. As in everything else in biology, alternate splicing is highly regulated, and its pattern can be specific to tissue, development stage, physiological condition, or disease.

A representative example of one kind of alternate splicing and its exploitation

Tab. 1 The principal types of RNA produced in cells.

Type of RNA	*Property*	*Transcribed by*
mRNA	Messenger RNA: codes for proteins.	RNAP II
rRNA	Ribosomal RNA: forms the basic structure of the ribosome and catalyzes translation.	RNAP I
tRNA	Transfer RNA: functions as adaptors between amino acids and mRNA during translation.	RNAP III
snRNA	Small nuclear RNAs: function in a variety of nuclear processes, including splicing.	RNAP III
snoRNA	Small nucleolar RNA: used to process and chemically modify rRNAs.	
SiRNA	Short interfering RNA: double-stranded RNA that eventually degrades target RNA in the RNA interference (RNAi) pathway; important in RNA therapeutics.	RNAP II
miRNA.	microRNA: related to siRNA in biogenesis. These and other small noncoding RNAs (ncRNAs) function in diverse cellular processes, including translation inhibition, X chromosome inactivation, telomere synthesis, and centromere silencing. Important in RNA therapeutics.	RNAP II

Intermediates and precursors are not described. For example, pri-miRNA is first processed by the nuclear RNase, Drosha, to produce pre-miRNA, which is further processed by Dicer in the cytoplasm to generate miRNA (Fig. 6). When first discovered, miRNA was called ''small temporal RNA'' (stRNA).

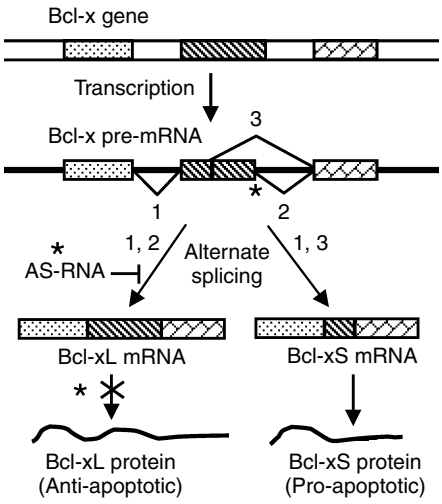

Fig. 2 Regulation of alternate splicing by antisense RNA Drug. The three possible splicing events on the Bcl-x pre-mRNA are labeled 1, 2, and 3. Combination of 1 and 2 splicing yields the short Bcl-xS mRNA and protein, while 1 and 3 splicing yields the long Bcl-xL mRNA and protein. The antisense RNA (AS-RNA, denoted by asterisk) inhibits splicing 3, thus blocking synthesis of the shorter protein and promoting death of cancer cells.

in therapeutics is shown in Fig. 2. Apoptosis or programmed cell death is regulated by differential expression of a large number of proteins by alternative RNA splicing, some of which may even have opposite apoptotic functions. For example, the Bcl-x pre-mRNA generates two alternative splice variants, namely, Bcl-x(long)

(Bcl-xL) and Bcl-x(short) (Bcl-xS). While the Bcl-xL protein is antiapoptotic, Bcl-xS is proapoptotic and sensitizes cancer cells to chemotherapeutic agents. Elevated levels of Bcl-xL generally correlate with decreased cellular sensitivity toward chemotherapy. In a recent approach, an antisense nucleic acid targeted to a complementary alternative splice site of Bcl-x pre-mRNA shifted splicing from Bcl-xL to Bcl-xS, thus lowering the apoptotic threshold of prostate cancer cells and increasing the efficacy of chemotherapeutic drugs. Thus, it is conceivable that a properly designed antisense RNA can selectively alter the splicing pattern of a pre-mRNA to produce a therapeutic effect.

In summary, an antisense RNA, by binding to a specific sequence, can alter the structure and function of the target RNA, which has obvious clinical implications. As discussed in the following sections (Sects. 1.4.2 and 1.4.3), ribozymes and siRNAs (Sect. 1.5) cannot inhibit site-specific splicing, but can be used to destroy a specific splice variant by targeting a sequence that is unique to the variant.

1.4.2 Trans-cleaving Ribozymes: Destruction of Undesired RNA

Ribozymes are RNA molecules that catalyze a chemical reaction, that is, scission of a covalent bond. Historically, the first catalytic RNA was described in a group I intron from *Tetrahymena thermophila* that could undergo self-cleavage (in cis), which was followed by the discovery of trans-cleaving RNA that could act on other RNA substrates. It was soon recognized that the latter class could be used as ''catalytic antisense'' tools in gene therapy, whereas the purely antisense RNA described above could only inhibit target function without causing loss of the target or alteration of the target sequence. By far, the most favored trans-cleaving ribozymes in clinical applications are the hammerhead ribozymes that share a typical secondary structure of the catalytic core composed of three helices and variable as well as invariant nucleotides at specific positions (Fig. 3a). Whereas helix II is formed intramolecularly, helices I and III are made of paired hammerhead and substrate sequences. Cleavage occurs 3′ to nucleotide H (Fig. 3a) of the target, and efficient cleavage requires a U to the 5′ side of this H to pair with a critical A residue (asterisked in Fig. 3a) in the hammerhead. The variable nucleotides (N in Fig. 3a) in these helices allow one to target virtually any RNA sequence. The repertoire of target sequences can be further expanded by taking advantage of noncanonical RNA base pairing and modified bases (Sect. 1.3). For example, replacement of the asterisked A (in Fig. 3a) with a more promiscuous base, inosine (I), resulted in a hammerhead ribozyme that could cleave at a CH consensus via I:C pairing. In summary, a synthetically engineered hammerhead ribozyme can act as ''molecular scissors'' destroying unwanted RNA of specific sequence such as a viral RNA, a splice variant, or a mutant RNA associated with a pathological condition such as cancer.

1.4.3 Trans-splicing Ribozymes: Repair of Defective RNA

Once defective genetic information has been transcribed into RNA, it is still possible to use RNA therapeutics to mend the defective RNA sequence without altering the DNA gene. Two major types of strategies have been developed that exemplify the use of trans-splicing ribozymes in RNA repair.

The first method (Fig. 4) employs the originally discovered self-splicing group I intron from *Tetrahymena*, which mediates

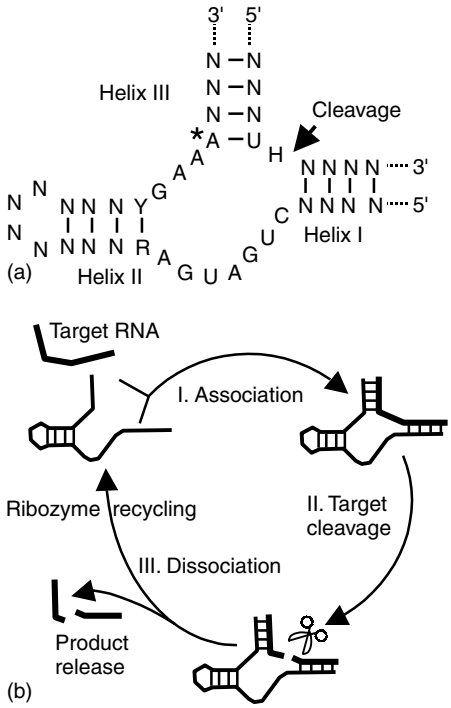

Fig. 3 (a) Secondary structure of a trans-cleaving hammerhead ribozyme with bound substrate. The ribozyme is in plain letters; substrate RNA is in bold. N = any nucleotide, Y = pyrimidine (U or C), R = purine (A or G), H = any nucleotide except G. Note that A:C and G:U base pairs are permissible in all RNA (Sect. 1.3), including ribozymes. The hammerhead ribozyme, associated with the substrate RNA, is depicted to form the three structurally and functionally important helices (I, II, III). In clinical applications, exogenously used hammerheads are generally 35 to 40 nt long, and the intramolecular helix II is formed by four base pairs; however, minimized hammerheads with faster cleavage rates have been described that contain only two base pairs in this helix. The cleavage site in the substrate RNA is as shown. The required UH dinucleotide is circled; this U can be substituted by a C if the pairing A (asterisked) is changed to I. (b) The target (thick line) cleavage cycle of a ribozyme (thin line). The dissociation step (product release) is the slowest and hence rate-limiting, but once dissociated from the cleaved target the ribozyme is recycled as a true catalyst to carry out multiple rounds of cleavage.

trans-splicing of an exon attached to its 3′ end onto a targeted 5′ exon RNA that is a separate RNA molecule. Repair of *lacZ* transcripts in *Escherichia coli* and in cultured mammalian cells using shortened versions of this ribozyme has been demonstrated. In such studies, the ribozyme, which is engineered to contain the wild-type sequence, base pairs with the mutant RNA using an internal guide sequence, cleaves off the mutant segment, and then ligates the wild-type sequence to the cleaved product (Fig. 4). In a variation of this theme, a "twin ribozyme" is created by tandem duplication of a hairpin ribozyme, such that four extra nucleotides are added to the replaced RNA segment. If this is an mRNA, then the resultant repaired mRNA would contain an extra amino acid followed by a frameshift, which may have a therapeutic value.

The second, related method is named spliceosome-mediated RNA trans-splicing (SMaRT) (Fig. 5), which does not require an exogenous ribozyme because it uses the spliceosome to catalyze a trans-splicing reaction between the target pre-mRNA and pre-trans-splicing RNA (termed PTM). Note that the PTM is not a ribozyme; its trans-splicing repairs the mutant RNA by simply competing with the natural cis-splicing.

In an interesting diagnostic application, "half-ribozyme" ligase molecules have

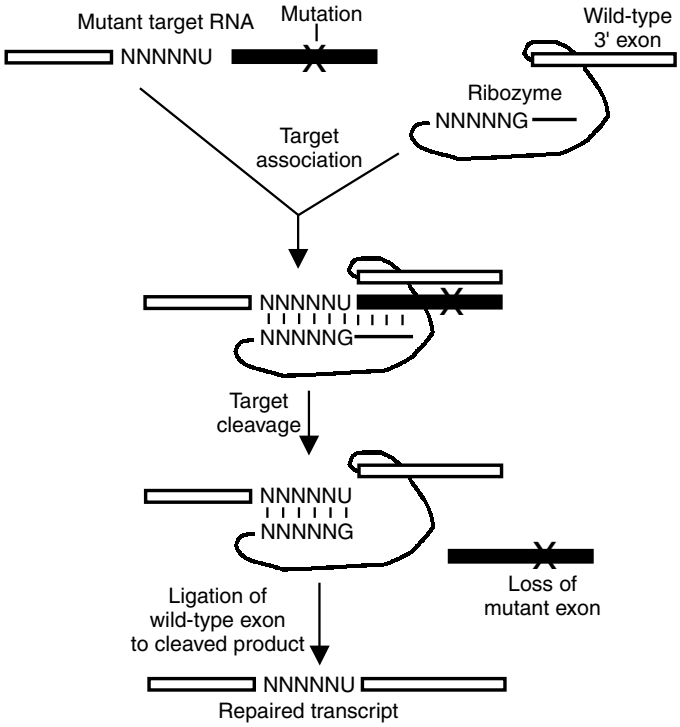

Fig. 4 Ribozyme-mediated repair of RNA. The mutant exon of the target RNA with the mutation X is shown in black. The trans-splicing ribozyme, introduced into the cell, brings in the wild-type exon (white). The N_5G stretch and some extra nucleotides acts as the internal guide sequence to direct trans-cleavage that results in the loss of the mutant exon and ligation of the wild-type exon to produce the repaired transcript (bottom).

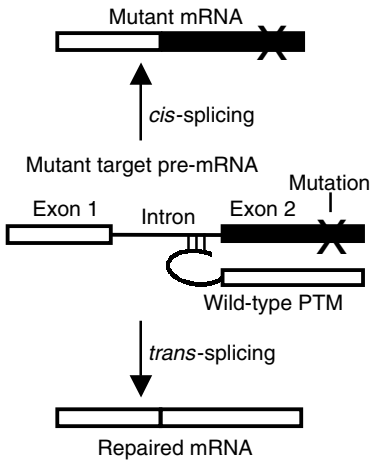

Fig. 5 Spliceosome-mediated trans-splicing repair of mutant RNA by SMART (Sect. 1.4.3). The mutant exon with the mutation X is shown in black and its wild-type counterpart in the PTM in white.

been designed that are activated upon binding to their RNA targets. The catalytic nature of these enzymes leads to multiple rounds of ligation, and hence signal amplification, allowing the detection of attomol (10^{-18}) quantities of the target, such as viral RNA in clinical samples.

1.5 RNA Interference: Sirna and miRNA

A relatively recent discovery, the phenomenon of RNA interference (RNAi) and the various aspects of its mechanism and application, has captivated the imagination of the biological community. A literature search through the PubMed site of NCBI (http://www.ncbi.nlm.nih.gov/) revealed that a total of 146 RNAi-related papers were published in just one month (May of 2004), averaging roughly five papers a day and underscoring the feverish activity in this field. The RNAi pathway is activated by double-stranded RNA (dsRNA), which, in principle, can form whenever sense RNA meets antisense. In nature, segments of many viral genomes are transcribed in both orientations, generating both sense (positive) and antisense (negative) RNA in the infected cell, which may then base pair to form dsRNA. In the laboratory, dsRNA can be synthesized chemically or by recombinant technology and then introduced into the cell, tissue, or animal. The mechanism of the RNAi pathway is briefly illustrated in Fig. 6, whereby a long dsRNA is precisely processed by Dicer, a member of the RNase III superfamily, to produce 21- to 28-nt long dsRNA fragments with 3′-overhangs, called siRNA. This step can be bypassed by chemically synthesized siRNAs that are directly introduced into the cell by transfection or electroporation. The siRNA is incorporated into a multiprotein complex called *RNA-induced silencing complex* (RISC), followed by unwinding of the strands by a helicase activity. The unwinding is asymmetric and initiates from the energetically easier terminus, that is, the one with the higher A–U base-pair

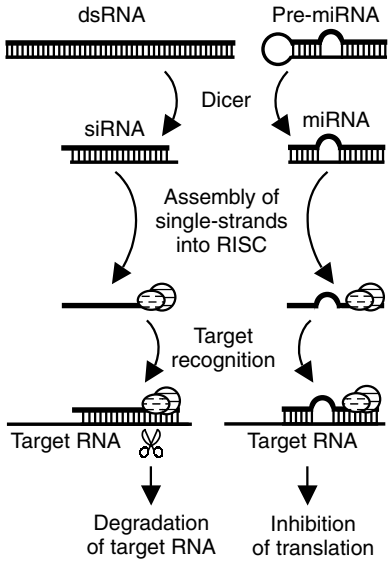

Fig. 6 RNA interference (RNAi). Only the major steps are shown. In contrast to siRNA, the miRNA starts as a hairpin and eventually inhibits the translation of an mRNA with imperfect match, although exceptions are known in that some miRNAs do degrade the target. The protein subunits of RISC are indicated by the spheres, but their exact number remains unclear. It is likely that the siRNA-RISC and miRNA-RISC assemble from common as well as unique subunits.

content. The activated RISC with the antisense strand engages its complementary target RNA. A RISC-associated RNase activity, the exact nature or composition of which remains unknown, then cleaves the target RNA 10 nucleotides from the 5′ end of the siRNA strand, resulting in knockdown or silencing of the corresponding gene function.

Recently, a related class of single-stranded cellular RNA, named microRNA (miRNA), has been discovered that is also 21- to 24-nucleotides (nt) long. They are transcribed from specialized endogenous genes as a ~70-nt-long hairpin precursor. The biogenesis and function of siRNA and miRNA are highly similar, although the full extent of overlap between the two pathways is yet to be determined. Dicer is involved in the processing of both from their respective precursors (Fig. 6), although different Dicers may be preferred by siRNA and miRNA. In general, it appears that siRNA and miRNA that are a perfect or a near-perfect match with their target degrade the target RNA, whereas those with mismatches repress translation instead, although a few exceptions are known. RISC is an exclusively cytoplasmic entity, and, therefore, siRNA and miRNA are only useful against cytoplasmic targets such as mRNA and not nuclear pre-mRNA. Viral genomic RNAs that are either highly structured or covered with protein are also resistant to RNAi.

The exact number of the small noncoding RNAs of the siRNA/miRNA family in the human cell is still unclear, but the current estimate runs in the hundreds. The accumulating evidence indicates that they regulate a variety of normal cellular pathways, including differentiation and development. Owing to their remarkable efficiency and selectivity, the siRNA and miRNA have emerged as major tools for knocking down gene expression in basic scientific as well as clinical applications.

1.6 RNA as a Protein Antagonist: SELEX, Aptamers, and Spiegelmers

The variability of nucleotide sequence and the ability to fold allow single-stranded DNA and RNA to attain a wide range of structures that can interact with high affinity and specificity with other biomolecules. In principle, starting with a large library of DNA or RNA sequences (about 10^{15}), one can select specific molecules or ''aptamers'' to bind to practically any target, such as a protein, by using a combinatorial and iterative Darwinian-type *in vitro* evolution process that has been termed SELEX for ''systematic evolution of ligands by exponential enrichment'' (Fig. 7). The aptamers are composed of a central randomized (degenerate) region flanked by fixed primer binding sites on either side for PCR-based amplification. Whereas antisense RNA and siRNA (Sect. 1.5) can target other RNAs only by Watson–Crick base pairing, the aptamers, in contrast, function by forming discrete structures that bind specific targets. Conceptually, aptamers are similar to antibodies in terms of specificity, but have several advantages over antibodies such as stability and chemical synthesis, as elaborated later (Sect. 1.8). Aptamers possess affinity in the low nanomolar to picomolar range and can discriminate between targets that are 96% identical in sequence. RNA aptamers derived from *in vitro* selections (SELEX) are being used inside cells for at least four purposes: (1) to antagonize cellular proteins; (2) as decoys to natural RNA-binding proteins; (3) as regulatory modules to govern gene expression; and (4) to antagonize nonprotein targets.

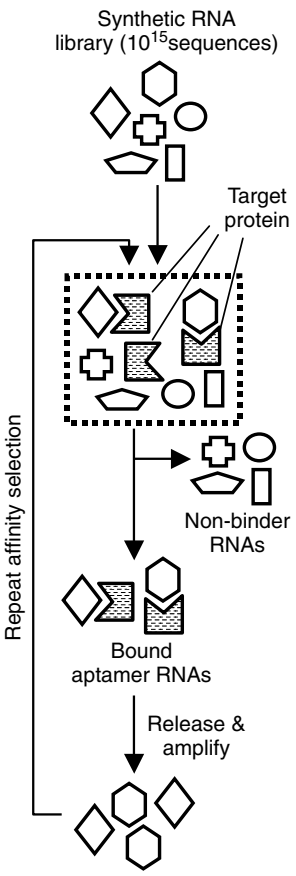

Fig. 7 RNA SELEX and aptamer. In this schematic diagram, the degenerate RNA molecules are depicted as pieces of various sizes and shapes, some of which fit the immobilized target protein (in gray). The unbound RNAs are discarded, and the bound aptamers are eluted and amplified by reverse transcription PCR. They can be further screened through additional cycles of binding and reamplification until the desired strength and specificity of binding is achieved.

Photoaptamers are defined as aptamers with photocross-linking functionality. Photocross-linking, so far, has never lowered the specificity and has, in fact, significantly increased it in some cases. Photoaptamers thus add a second dimension of specificity, since they recognize both the complex shape and charge distribution of their targets and the presence of specific amino acid residues at specific sites.

Spiegelmers (German: "Spiegel", means "mirror") are mirror-image aptamers made of L-nucleotides. The L-enantiomers act just like standard aptamers but have the added advantage of being highly biostable owing to their resistance to nucleases.

1.7 Polyamide ("Peptide") Nucleic Acid (PNA)

PNA (polyamide ("peptide") nucleic acid) is a synthetic nucleic acid analog in which the entire phosphate sugar backbone is replaced by an uncharged polyamide (peptide-like) backbone that is nuclease-resistant. The side groups are still the natural purine and pyrimidine bases and are in similar configuration as in natural single-stranded nucleic acids. Thus, PNAs possess the base-pairing capability and specificity of nucleic acids and hence can function as antisense, but are more stable and bind more strongly and specifically to their DNA or RNA targets.

A unique property of some PNA sequences is to function as antigenes. These PNAs bind to double-stranded DNA by an invasion mechanism; two PNA molecules form a triplex structure with the complementary DNA target sequence, whereas the other strand of the DNA duplex is displaced into a single-stranded loop. Although this type of binding is generally limited to pyrimidine-rich sequences, the resulting PNA–DNA complex is extremely stable. If this happens at the promoter or enhancer sequences, binding of RNAP

or specific transcription factors can be abrogated in cis, leading to silencing of specific genes.

1.8 Summary: Pharmaceutical Advantages of RNA

The relevant advantages of RNA over other forms of traditional and prospective pharmaceuticals are summarized in Table 2. Proteins contain 20 different amino acids, each with its unique chemical and physical property. RNA (or DNA), in contrast, is made of only four nucleotides, thus reducing the complexity. The costs of chemical synthesis of the three biological macromolecules of the Central Dogma are currently in the order: Protein > RNA > DNA. Recombinant expression of protein is an uncertain prospect due to a variety of factors such as mRNA and protein stability and processing, translational regulation, and codon bias. Finally, biological activity of many proteins requires posttranslation modifications such as glycosylation and phosphorylation that do not occur in bacterial expression systems. Purification of proteins in active form can be a significant hurdle due to insolubility and improper folding. A drawback of DNA is the ability of its CpG motifs to activate toll-like receptors and thus induce a general innate immune response, which, in fact, underlies the apparent therapeutic effects of several successful antisense DNA molecules.

Small molecules currently constitute the largest class of drugs and owe their origin to two major sources: natural products, often from folklore, and structure-based drug design. The former is subject to the whims of serendipity and nature's bounty, and the latter requires expensive cutting-edge technology. Synthesis of small-molecule drugs by chemical means has been the norm of the pharmaceutical industry, but the chemical reactions are often challenging and need to be revised for every new compound or new substitution. RNA can be rather easily made *in vitro* as well as *in vivo* by transcription from cloned cDNA. Small RNA molecules, such

Tab. 2 The unique advantage of RNA as pharmaceutical.

Relevant property	*DNA*	*RNA*	*Protein*	*Small molecule*
Chemical synthesis and modification	Yes	Yes	Difficult	Some

Relatively low cost	Yes	Yes	No	No

as siRNA, are better made chemically, and one can expect that the cost will diminish with innovative chemical and process engineering and increased market volume.

Ribozymes and siRNAs are likely to be the major RNA weapon of the future in our war against pathogenic RNA. There are multiple advantages to targeting RNA instead of proteins including sequence-specific binding, a greater number of sites accessible for interaction, selective inhibition, exploitation of multivalent interaction, and more facile attack on drug resistance. RNA's link to genomics and bioinformatics also allows for increased discovery and specificity testing.

2 Emerging Clinical Applications of RNA

2.1 Ribozymes Against Infectious Agents

One of the first obvious viral targets for ribozyme therapy is HIV-1, causative agent of AIDS, due in part to the extraordinary death toll of the disease and the limited efficacy and toxicity of the multidrug cocktails targeting the viral reverse transcriptase. Various sequences in the HIV genome can be targeted for ribozyme-mediated therapy. The two types of ribozymes (hairpin and hammerhead) show similar antiviral efficacy in cell culture in terms of their ability to inhibit the HIV replication and fare well in clinical trials as well. In representative studies, autologous lymphocytes were transduced with a hairpin ribozyme that cleaves the U5 region of HIV-1 RNA, and the resulting cell population consisting of transduced and nontransduced cells was infused. When tested in peripheral blood, the ribozyme-containing cells indeed exhibited preferential survival over non-ribozyme-containing cells. Similarly, hammerhead ribozymes targeted to a conserved region of the HIV *tat* gene (*Rz2*) were transduced into a population of syngeneic CD4+ T lymphocytes. Four patients, infused with syngeneic lymphocytes and subsequently tested by PCR analysis showed hammerhead expression and viral inhibition up to 4 years postinfusion (the latest time point examined). These procedures were well tolerated with no serious adverse events. Together, these results indicate that infusion of gene-altered, activated T cells in HIV-infected patients is safe, and that transduced cells persist for long intervals. Results also suggest that ribozyme-transduced cells may possess a survival advantage *in vivo*.

A different approach for ribozyme gene therapy is to transfer the ribozyme expressing constructs into hematopoietic stem cells of human immunodeficiency virus-1 (HIV-1)-infected individuals. This might be a potent therapeutic approach to provide mature cells arising from transduced stem cells resistant to the destructive events associated with HIV-1 infection. To determine the feasibility of gene therapy for AIDS patients, peripheral blood $CD34^+$ cells were isolated from HIV-1-infected individuals and transduced with retroviral vectors containing three different anti-HIV-1 genes: the RNAbinding domain of the Rev-responsive element (RRE decoy) (L-RRE-neo), a double hammerhead ribozyme vector targeted to cleave the Tat and Rev transcripts (L-TR/TAT-neo), and a trans-dominant mutant of Rev (M10) (L-M10-SN). As a control, a vector mediating only neomycin resistance (LN) was used. After 3 days of transduction on allogeneic stroma in the presence of stem cell factor, and cytokines interleukin-6 (IL-6) and IL-3, the cultures were neomycin-selected, and then challenged with HIV-1.

Compared to the control cultures, the L-RRE-neo-, L-TR/TAT-neo-, and L-M10-SN-transduced cultures displayed up to 1000-fold inhibition of HIV-1 replication after viral challenge. This study shows that anti-HIV-1 genes can be introduced into $CD34^+$ cells from individuals already infected with HIV-1, and that they strongly inhibit HIV-1 replication *in vivo*.

Herpes simplex virus 1 (HSV-1) and human cytomegalovirus (HCMV) are pervasive herpes viruses that cause severe morbidity or mortality in neonates and immunocompromised individuals. In particular, HSV-1 is the causative agent for cold sores and encephalitis in newborns. HCMV is one of the leading causes of birth defects in the United States and is accountable for more than 50% of deaths in organ transplant patients; furthermore, HCMV retinitis is the leading cause of AIDS-related blindness. In recent studies, ribozymes efficiently cleaved mRNAs of both viruses and effectively reduced viral growth in cultured cells. Targeting of the mRNA encoding the major transcriptional activator ICP4 of HSV-1, an immediate-early gene that is essential for the expression of most of the viral early and late genes, caused about 80% reduction in ICP4 and a 1000-fold decrease in viral growth. Meanwhile, other immediate-early gene (e.g. α47 and ICP27) expressions were not affected, showing that the ribozyme is highly specific in targeting the desired mRNA. Ribozyme expression was not cytotoxic, and the expressing cells were indistinguishable from the parental cells in terms of cell growth and viability for up to 2 months. Similar results were also seen when the overlapping region of HCMV immediate-early gene 1 and 2 (IE1/IE2) was targeted by ribozyme. In HCMV-infected human cells, this ribozyme reduced IE1/IE2 expression by 85% and inhibited HCMV growth 150-fold. Reduction of IE1/IE2 expression levels also resulted in the downregulation of other early and late gene products such as US2, UL44, gB, and gH, whereas transcripts that are not regulated by IE1/IE2 (e.g. 5 kb RNA and UL36 mRNA) were unaffected.

Hepatitis C virus (HCV) infection may lead to chronic hepatitis, cirrhosis, and hepatocellular carcinoma. Therapy of chronic HCV infection has greatly improved with the combined use of ribavirin and α-interferon, and, recently, PEG-interferons. However, more than half of the patients do not accrue lasting benefits from these therapies. Ribozyme strategies to target certain HCV sequences have been proposed as anti-HCV treatments. Specifically, the 5′ noncoding region of the HCV RNA is highly conserved and plays an essential role in translation initiation by functioning as an internal ribosome entry site. In several studies, endogenously expressed as well as exogenously delivered ribozymes targeted against this region inhibited HCV replication. In 2000, Ribozyme Pharmaceuticals, Inc (now Sirna Therapeutics) and Eli Lilly and Company completed a 28-day study of Heptazyme following daily subcutaneous injections that showed successful safety, tolerability, and pharmacokinetics. In 2001, phase-2 clinical trials began, designed to evaluate the safety and efficacy of Heptazyme alone and in combination with interferon. Initial results showed that 10% of Heptazyme recipients experienced biologically meaningful reductions in serum HCV RNA levels. In 2002, however, the trial was halted due to blindness that occurred in one animal 12 months after receiving high-dose Heptazyme during toxicology testing.

Urogenital human papillomavirus (HPV) infections are the most common sexually transmitted viral diseases

in women. Recently, a self-processing triple-ribozyme cassette, consisting of two cis-acting hammerhead ribozymes flanking an internal trans-acting hammerhead (ITRz), was tested against HPV-11 E6/E7 mRNA, whereupon significant reductions (80–90%) were achieved for both. A similar ribozyme, designed against hepatitis B virus (HBV), caused a >80% reduction in viral liver DNA in two weeks in a transgenic mouse model.

2.2 Ribozymes Against Cellular Disorders

Recently, ribozymes have been demonstrated as a highly effective treatment against a number of cellular disorders and especially cancer. Point mutations in the K-*ras* gene are observed at a high incidence in human pancreatic carcinomas. Anti-K-*ras* ribozyme against codon 12 of the mutant K-*ras* mRNA, when expressed via a recombinant adenoviral vector, suppressed tumor growth and promoted regression. It was also possible to accomplish efficient reversion of the malignant phenotype in human pancreatic tumors with K-*ras* gene mutation.

It is well known that tumor growth beyond a few cubic millimeters does not occur without the induction of a new vascular supply network, known as *angiogenesis*. Inhibition of angiogenesis has been heralded as a potential approach to cancer therapy. Vascular endothelial growth factor (VEGF) is the best-characterized proangiogenic factor, and effective blockade of the VEGF pathway has been demonstrated with multiple agents such as neutralizing antibody, receptor tyrosine kinase inhibitors, and ribozyme or antisense molecules. Promising preclinical data document the potential of these agents for tumor growth inhibition and even tumor regression, yet translation of novel therapeutics targeting the VEGF pathway to the clinic has proved a substantial challenge in itself. Angiozyme, developed by Sirna Therapeutics, specifically inhibits formation of the vascular endothelial growth factor receptor (VEGFR-1), a key component in the VEGF pathway. This drug is currently in clinical trials for several cancers, including breast and colon cancers. There have been no significant toxicities related to drug use in trials reported and the occurrence of side effects has been low.

Hepatocyte growth factor/scatter factor (HGF/SF) elicits a number of biological activities, including invasion and migration through activation of its tyrosine kinase receptor c-Met, overexpression of which is implicated in prostate cancer development and progression. Targeting the HGF/SF receptor by way of a hammerhead ribozyme is considered an important therapeutic approach in these cancers.

Ribozyme has been particularly useful in targeting oncogenic mRNAs resulting from random chromosomal translocation. For example, translocation between chromosome 9 and 22 fuses the genes of BCR and c-ABL to produce BCR-ABL, resulting in chronic myelogenous leukemia (CML). Ribozymes with the guide sequences that target the fused sequence of the transcript effectively destroys the BCR-ABL fusion transcript found in the cancerous cells of leukemia patients. More importantly, the inhibition is highly specific, as the ribozyme only cleaves the targeted chimeric transcript, but not the normal cellular counterpart, thus making this a promising approach in cancer therapy.

In the management of asthma, hammerhead and hairpin ribozymes targeting conserved sequences within IL-4, IL-5, ICAM, and NF-κB mRNA have been already designed. Pharmacokinetics in mice

revealed that when administered intratracheally, these ribozymes have improved therapeutic benefits compared to traditional drugs.

2.3 RNAi Against Viruses

RNAi-mediated inhibition of virus replication in animal cells was first reported by our laboratory only three years ago using respiratory syncytial virus (RSV) as a prototype model, which opened up a new direction in antiviral drugs. RSV, an RNA virus, is a major cause of respiratory infection in infants and the elderly, and claims a few millions lives throughout the world annually. To this date, there is no reliable vaccine or antiviral. Use of siRNA against essential RSV transcripts inhibited virus growth in cultured lung epithelial cells and, recently, in a mouse model. Silencing of the RdRP subunits, L and P, reduced the progeny viral titer 10^3 to 10^4 fold. No cytopathic effect has been detected in uninfected siRNA-treated cells. A number of viruses have since been targeted by siRNA *in vitro* as well as *in vivo* with highly encouraging results.

As implied earlier, HIV-1 often escapes commonly used therapies because of its high mutation rate and the complexity of the pathogenesis of AIDS. RNAi, targeting various HIV sequences that encode the structural proteins Gag and Env, the reverse transcriptase, the regulatory proteins Tat and Rev, and two accessory proteins Nef and Vif, were all effective to various degrees in inhibiting HIV growth. RNAi targeting of nontranslated RNA sequences in the long terminal repeats (LTRs) of HIV, which contains important regulatory elements required for HIV replication, was also effective. In principle, one can also inhibit virus infection by silencing the expression of essential cell factors that are critically involved in viral life cycle. Inactivation of the cellular receptor (CD4) and coreceptor (CXCR4, CCR5) by specific siRNA, in fact, reduces HIV infection of T cells.

Influenza A virus causes widespread infection in the human respiratory tract, but existing vaccines and drug therapy are of limited value. siRNAs, against influenza's nucleocapsid or a component of RdRP, abolish viral transcription and replication in cell lines and embryonated chicken eggs. These results should provide a basis for the development of siRNA as preventive treatment and therapeutic drug for influenza infection in humans.

RNAi has also been used against several other viruses, including Dengue virus, flock house virus (FHV), rhesus rotavirus (RRV), Semliki forest virus (SFV), and poliovirus. All hepatitis viruses, for example, hepatitis B (HBV), C (HCV), and delta (HDV), are major public health hazards; RNA interference appears to be an attractive option against them. siRNA against the core region of HBV, when cotransfected with the full-length HBV DNA into Huh-7 and HepG2 cells, effectively inhibited viral growth in cell culture and mice. Essentially, similar results were obtained with siRNA against the *S* gene of HBV. HCV, a *Flaviviridae* with a small RNA genome, is a uniquely difficult virus to study because of the lack of *in vitro* cell culture models. However, recently, subgenomic replicon systems for HCV have been developed using siRNAs against viral NS3 and NS5B as well as against the 5′-UTR, and they were shown to effectively inhibit viral replication. In HDV, recent studies showed that the delta antigen mRNA can be successfully targeted by siRNAs in cell culture.

In contrast to viral mRNAs, the genomic and antigenomic RNAs of many viruses are resistant to siRNA action. This is either due to their encapsidated nature (as in negative-strand RNA viruses) or possibly due to extensive secondary structure (as in HDV). Early studies had indeed confirmed that the RNAi machinery is exclusively cytoplasmic and fails to knock down unexported nuclear pre-mRNA.

2.4 RNAi as an Antiparasitic Approach

Parasites are lower eukaryotes and cause diseases of considerable medical and veterinary importance throughout Africa, Asia, and the Americas. The advantages of RNA interference have offered new hope, and siRNA drugs have indeed caused substantial inhibition of a number of parasites in the last few years. Among the parasites where RNAi has been extensively demonstrated is the protozoan parasite, *Trypanosoma brucei* (African sleeping sickness), and *Schistosoma* or flukes (liver, kidney, and intestinal damage). It should be noted, however, that the exact mechanism of siRNA action in many parasites remains to be elucidated.

The Apicomplexan parasite, *Toxoplasma*, can cause blindness, mental retardation, and miscarriage. We have recently discovered that the genome of *Toxoplasma gondii* contains orthologs with significant similarity to traditional RNAi-related genes, such as Argonaute, Dicer, RdRp, and various RDE-related genes. Expression of dsRNA, homologous to parasitic uracil phosphoribosyltransferase (UPRT) mRNA, but not of antisense RNA alone, was shown to downregulate the function of the corresponding enzyme. However, the connection of these results with the RNAi pathway needs to be established. RNAi-like phenomena were also reported in *Plasmodia* (another Apicomplexan parasite and causative agent of malaria), but the mechanism(s) remain uncertain because of the absence of any obvious orthologs of the RNAi pathway. Validation of the RNAi pathway will provide a major breakthrough in the genetic manipulation of these otherwise difficult organisms.

Vector-borne infections, including many mosquito-borne viruses and arboviruses, in general, pose a tremendous burden to the human society, particularly in the developing countries. Studies have shown that RNAi can be used to knock down gene expression both in the adult mosquito and immortalized cell lines. The RNAi mechanism could potentially be used to develop transgenic vectors that provide innate resistance to the development and growth of arthropod-borne pathogens. To explore RNA silencing in disease vectors, new studies have taken advantage of the recent completion of genome sequence of *Anopheles gambiae*, the main vector for human malaria in Africa. Homology searches revealed two Dicer-like and five Argonaute-like genes in *A. gambiae*. siRNA directed against mRNAs of these representative genes indeed caused a reduction of RNAi efficiency in *A. gambiae* Sua1B cells, confirming their functional role. Thus, RNAi may become a widely undertaken approach in mosquito management.

2.5 RNAi Against Genetic Disorders and Cancer

The fastidious sequence-specificity of siRNA allows one to specifically target the dominant and codominant mutations that underlie many noninfectious diseases. Recently, siRNAs have proven

highly effective against a number of genetic abnormalities such as autoimmune diseases, asthma, AMD, diabetes, and diabetic retinopathy, CNS disorders, obesity, ALS or Lou Gehrig's disease, and various forms of cancer.

Specific inhibition of the oncogenic K-RAS V12 expression in human tumor cells by siRNA resulted in loss of anchorage-independent growth and tumorigenicity. Since siRNA-mediated gene silencing is highly sequence-specific, siRNA can be designed to silence cancer-derived transcripts that harbor point mutations. The guardian of the genome, p53, is inactivated by point mutation in >50% of human cancers. A single base difference in siRNA discriminated between mutant and wild-type tumor suppressor p53 in cells expressing both forms, resulting in the restoration of wild-type protein function.

Unnatural fusion proteins are relatively common in cancer. Transfection of leukaemic cells with siRNAs targeting a BCR–ABL (breakpoint cluster region – Abelson protooncogene) fusion transcript induced apoptosis comparable to that triggered by the ABL tyrosine kinase inhibitor STI571 (signal transduction inhibitor 571). In Ewing's sarcoma, the transcription factor EWS is fused to a variety of other transcription factors such as FLI and Ets at various breakpoints. The NPM-ALK fusion protein, for example, is found in about 75% of pediatric anaplastic large cell lymphomas. Specific siRNA drugs designed against such chimeric mRNA may constitute a potent and specific form of anticancer therapy. Osteosarcoma is the most common highly malignant bone tumor with primary appearance during the second and third decades of life. It is associated with a high risk of relapse, often resulting from resistance developed to chemotherapy agents. Interestingly, the apurinic endonuclease 1 (APE1) is usually overexpressed in human osteosarcoma. Using siRNA against APE1, protein levels were reduced by more than 90% within 24 h, remained low for 72 h, and returned to normal levels at 96 h. There was also a clear loss of APE1 endonuclease activity following APE1-siRNA treatment. A decrease in APE1 levels in siRNA-treated human osteogenic sarcoma cells led to enhanced cell sensitization to DNA damaging and chemotherapeutic agents, thus improving prognosis.

At least eight human neurodegenerative disorders, including Huntington's disease (HD) and spinobulbar muscular atrophy (SBMA) (Kennedy's disease), are caused by expansion of trinucleotide repeats, most common among which is the repeat of the CAG codon, coding for glutamine. Transfection of cells expressing the CAG-expanded androgen receptor mRNA shows response to siRNA treatment by a reduction in mutated RNA level and, more importantly, by a rescue of the polyglutamine-induced toxicity. This example represents a proof of principle to apply siRNA technology to diseases associated with mutated transcripts arising from one allele (e.g. other neurodegenerative disorders) without affecting the other (healthy) allele.

Recently, anti-VEGF siRNAs have received much attention owing to their efficacy in preventing angiogenesis. In the mouse model, targeting VEGF by injecting siRNA into tumors resulted in growth inhibition, tumor cell killing, and sensitization of the treated cells to other therapies. Anti-VEGF siRNAs therapy of age-related macular degeneration (AMD) and diabetic retinopathy (DR) is a major area of pharmaceutical interest.

2.6 Antisense RNA in Therapy

Antisense (AS) therapy has been widely used to specifically and selectively inhibit the expression of selected genes at the mRNA level. Use of AS-RNA against cancer-associated mRNA may lead to specific protein silencing and death of the cancer cells. Indeed, the anti-apoptotic protein Bcl-2 and telomerase were both successfully silenced in cultured cells, leading to cell growth inhibition. The insulin-like growth factor 1 receptor (IGF-1R) is an important signaling molecule in cancer cells and plays an essential role in the establishment and maintenance of the transformed phenotype. Inhibition of IGF-1R signaling thus appears to be a promising strategy to interfere with the growth and survival of cancer cells. AS-RNA, designed to inhibit IGF-1R gene expression, efficiently reduced IGF-1-dependent proliferation and survival in a number of human and rodent cancer cell lines. Furthermore, a decrease in tumor size occurred when cells carrying the AS-IGF-1R were injected into syngeneic mice. In addition to blocking tumor growth, the AS-RNA treatment also inhibited metastasis. Many other genes have been selected as targets for AS-therapy, including HER-2/neu, PKA, TGF-α, EGFR, TGF-β, P12, MDM2, BRCA, Bcl-2, ER, VEGF, MDR, ferritin, transferrin receptor, IRE, C-fos, HSP27, C-myc, C-raf, and metallothionein. In many of these studies, specific inhibition of tumor cell growth was demonstrated. Combinations of AS-RNA with chemotherapeutic agents may offer important advantages in cancer treatment. Several antisense drugs, especially Oblimersen (G3139), have shown promising results in animal experiments, and have entered clinical trials.

2.7 RNA Aptamers in Therapy

Several highly specific, nucleic acid aptamers targeting select HIV proteins have been described that effectively blocked viral replication. Aptamers directed against HIV-1 Rev protein were tested in a surrogate animal model harboring human tissue. In the SCID-hu mouse *in vivo* human thymopoiesis model, differentiated thymocytes derived from reconstituted grafts expressed anti-Rev aptamers and showed significant resistance to HIV-1 infection upon challenge.

Blood clotting, which can trigger heart attacks and strokes, is a significant area of RNA aptamer application. Although anticlotting drugs are currently available, most have serious drawbacks. For example, heparin and its antidote, used during and after surgery respectively, can often cause adverse reactions; the dosage of another common blood-thinning drug, Warfarin, is difficult to regulate, and it has no antidote. One trillion RNA aptamers were recently screened for the ability to block specific protein factors crucial to the blood clotting process. Once a clot-stopping aptamer was chosen, its antidote was also designed, which is simply another length of RNA with a complementary sequence. This second RNA snippet sticks to the first, disabling it. In the test tube, different amounts of antidote either regulated or reversed the aptamer's anticlotting ability. Studies in animals are now under way.

The treatment of immunomediated glomerulonephritides is presently based upon a limited series of drugs. Several original and innovative approaches to treat inflammatory glomerular diseases have been recently reported, including RNA drugs designed to limit the

effect of proinflammatory and prosclerotic cytokines. The application of peptide aptamers specifically binding to the IGF-1R represents a novel approach to target IGF-1R signaling in cancer. Integration of peptide aptamers into targeted protein degradation vehicles and their transduction into cells allows the temporary elimination of the receptor protein.

Myasthenia gravis is a neuromuscular disorder associated with muscular weakness and fatigability. The pathogenesis of MG mainly results from antibody-mediated autoimmune response to nicotinic acetylcholine receptors (AChR) located in the postsynaptic muscle cell membrane. Recently, aptamers were successfully used to treat experimental autoimmune myasthenia gravis (EAMG) in animals. Clinical symptoms of EAMG in rats were efficiently inhibited by a truncated RNA aptamer, but not by control scrambled RNA. Moreover, the loss of AChR in the animals induced by the antibody was also significantly blocked with the modified RNA aptamer.

Aptamers can also be used against parasites. African trypanosomes cause sleeping sickness in humans and Nagana in cattle, multiply in the blood and escape the immune response of the infected host by antigenic variation, that is, periodic change of the parasite surface antigen, which consists of a variant glycoprotein known as *variant surface glycoprotein* (VSG). Aptamers that bind to VSGs with subnanomolar affinity are able to recognize different VSG variants and bind to the surface of live trypanosomes. Aptamers tethered to an antigenic side group are capable of directing antibodies to the surface of the parasite *in vitro*.

2.8 Spiegelmers in Therapy

Spiegelmer that inhibits the action of the migraine-associated target calcitonin gene-related peptide 1 (alpha-CGRP) was identified as a lead compound for *in vivo* studies. Gonadotropin-releasing hormone (GnRH) is a key peptide hormone in the regulation of mammalian reproduction. It is the trigger signal for the cascade of hormones responsible for controlling the production of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone. GnRH and its receptor, therefore, have been identified as therapeutic targets for sex steroid–dependent conditions such as prostate cancer, breast cancer, and endometriosis, as well as in assisted-reproduction techniques. A spiegelmer with high affinity for gonadotropin-releasing hormone (GnRH) was isolated that acted as an antagonist to GnRH in Chinese hamster ovary cells stably expressing the human GnRH receptor. In a castrated rat model, the spiegelmer further demonstrated strong GnRH antagonist activity. These studies suggest that spiegelmers could be of substantial interest in the development of new pharmaceutical approaches against GnRH and other targets.

2.9 PNA in Therapy

PNAs demonstrated significant promise against papillomavirus-induced human cancers. Approximately 100% of cervical carcinomas are caused by infections with human papillomaviruses (HPVs). The expression of the *E6* and *E7* genes from high-risk HPV16 and 18 is crucial for development, immortalization, and maintenance of the malignant phenotype

of cervical carcinoma, and constitutes important targets for anticancer therapies. Different PNAs directed against HPV18 *E6* and *E7* genes were able to regulate the growth of HeLa-S cervical cancer cells. Telomerase activity, which is below detectable level in almost all types of diploid cells, is re-activated in most immortal and cancer cells. In recent studies, PNAs directed against the human telomerase RNA (hTR) and catalytic subunit (human telomerase reverse transcriptase, hTERT), effectively arrested the growth of gastric cancer cells. In another study, upregulation of the *c-myc* oncogene in Burkitt's lymphoma cells was inhibited by PNA complementary to a specific unique E mu intronic sequence and blocked the expression of the *c-myc* oncogene under E mu control.

PNAs were also effective antivirals. The RNA genome of HCV contains a well-defined and highly conserved secondary structure that functions as an internal ribosomal entry site (IRES), necessary for translation and viral replication. PNAs can invade critical sequences within the HCV IRES and thereby inhibit translation. In cells infected with pseudotyped HIV-1 virions, PNAs exhibited dramatic reduction of HIV-1 replication.

2.10 Immunotherapy by RNA

With the realization that cancer or malignant tumor is a disease of defective genetic programming, attempts have been made to identify tumor-specific proteins and train the body's immune system against these prospective antigens. The strategy of immunotherapy of cancer is based on the knowledge that nonself (or foreign) proteins are proteolytically degraded inside bone marrow–derived dendritic cells (DCs) to produce short peptides that associate with the major histocompatibility complex (MHC) and are transported to the cell surface. Naïve cytotoxic T cells (CTLs) recognize the displayed peptide–MHC complexes and undergo an activation process to kill the targets. In the cancer patient, the capture of tumor antigens by DCs and/or the stimulation of tumor-specific CTLs is apparently inefficient. In RNA immunotherapy, the strategy is to transfect DCs with mRNA for specific tumor antigens or with total tumor-derived mRNA population, and introduce them into the patient. In animals as well as human volunteers, DCs loaded with tumor mRNAs indeed stimulated CTL response. As with other mammalian cells, cationic lipid reagents and electroporation have been used for mRNA transfection into DCs; interestingly, mRNA alone is effective, which reflects the extraordinary sensitivity of the immune system to small amounts of antigen. The success of the mRNA loading obviates the need for difficult and laborious alternatives such as cloning the mRNAs into cDNA or expression and purification of tumor-specific proteins. In fact, in direct comparison, mRNA-loaded DCs often fare better than those transfected with cDNAs or proteins. Endosomal compartments of DCs also contain specialized toll-like receptors that are activated by single-stranded RNA, resulting in the activation of IFN-γ. This apparent side effect can be actually beneficial for therapy against viruses and cancer. RNA immunotherapy does not require an understanding of the mechanism of tumorigenesis, and yet offers a natural and biological anticancer treatment that can be custom-designed and administered against a particular tumor in a matter of hours.

3
Design, Synthesis, Delivery, and Pharmacokinetics of RNA

3.1
Design and Synthesis of an Effective RNA Drug

A number of algorithms and software have been developed to design ribozymes, siRNA, and aptamers, and analyze their interaction with prospective targets *in silico*, although many of them are based on semiempirical and thermodynamic studies such that the final selections must be experimentally tested for efficacy. Many such programs and other RNA-related resources are available at various web sites.

The principles of Ribozyme design have been discussed (Sects. 1.4.2 and 1.4.3). The siRNAs are 21- to 23-nt-long, double-stranded RNA with 2-nt overhangs. Synthetic siRNAs are generally made to conform to the sequence $NA(N)_{19}TT$ where N can be any nucleotide; however, variations of the overhangs have been tried with success. The $(N)_{19}$ core should be perfectly complementary to the target RNA sequence, but some mismatch may be tolerated, especially if it occurs near the termini of the siRNA. Recently, a set of eight rules has been suggested for rational design of the $(N)_{19}$ core of the siRNA on the basis of experimental analysis and thermodynamic annealing parameters. A few important ones are as follows: 30 to 52% GC content, absence of internal repeats or hairpins, and, most importantly, three or more A/Us at positions 15 to 19 of the sense strand so that preferential unwinding occurs from this end of the siRNA duplex, resulting in the formation of a RISC with the antisense strand (Fig. 6). siRNA and degradative ribozymes should be designed away from the 5′ and 3′ termini of the target mRNA as these regions interact with, and are protected by, translational machinery or factors.

RNA can be synthesized either exogenously (*in vitro*) and then delivered into cells, or transcribed endogenously (*in vivo*) from DNA clones introduced into cells. Exogenous RNA can be made using synthetic chemistry or by transcription of DNA clones. A major issue in the therapeutic use of RNA is its stability. The only difference between DNA and RNA (besides the T to U change) is the 2′-OH group of the ribose ring in the RNA. This has important consequences, the most prominent of which is the hydrolysis of the phosphodiester bond of the RNA catalyzed by nucleophilic attack of the electrons of the extra oxygen atom – fundamentally the same reaction that is catalyzed by ribozymes. A major effort in synthetic RNA chemistry is, therefore, directed toward modifying the 2′-OH group. An ideal modification must provide improved stability and better pharmacokinetics without affecting the base-pairing characteristic or function of the RNA. Notable modifications include amino, fluoro, methyl, and allyl derivatives of the 2′-OH group. Another common modification is to replace the oxygen atoms of the phosphodiester bonds by sulphur. The resulting phosphothioester bond is unhydrolyzable, but it is now realized that the phosphorothioate RNA exhibit significantly higher cellular toxicity and nonspecific binding to proteins. The current trend is to use a limited number of phosphorothioate linkages combined with 2′-modifications. In another approach, an inverted T is added at the 3′ end to form a 3′-3′ phosphodiester linkage, which makes the RNA resistant to 3′ exonucleases. In designing a siRNA, deoxythymidines (dT) are used to substitute for the two T overhangs with the hope of

increasing the nuclease-resistance at the 3′ end. Ribozyme cores are also susceptible to hydrolysis by endonucleases that primarily attack the pyrimidine nucleotides. Thus, 2′-modification of the two U nucleotides of the CUGAUG consensus (Fig. 3a) produces a more stable hammerhead without compromising ribozyme activity. In yet another approach, deoxyribozymes have been developed that exhibit some advantages over RNA ribozymes, such as greater stability, improved catalytic efficiency, and potentially lower toxicity.

Clearly, chemical modifications are only possible *in vitro* and not *in vivo*, when the RNA is being produced through transcription inside a cell. On the other hand, *in vivo* synthesis of RNA from recombinant DNA clones obviates the need for manufacturing and delivering the RNA and uses the natural transcriptional machinery of the target cell itself. The RNA is only produced inside the cell, thus avoiding losses in blood and degradation by serum nucleases. A variety of vectors have been used for *in vivo* expression of RNA, the most common ones being either plasmids or viral vectors with strong promoters. Small RNA molecules such as ribozymes and siRNA are often transcribed from a RNAP III promoter engineered into these vectors, such as the U6, H1, or 7SK promoters of mouse or human origin. Controlled expression of RNA is often achieved through the use of inducible and tissue-specific promoters.

Like small molecules, RNA drugs are highly amenable to automated high-throughput screening (HTS) procedures, based either on direct binding to targets or function-based alteration of reporter gene expression. Combined with chemical modification of synthetic RNA, such assays can be adapted to use almost any kind of readout format, including, but not limited to, fluorescence intensity (FI), fluorescence lifetime (FLT), fluorescence polarization (FP), fluorescence resonance energy transfer (FRET), solid-state (membrane or bead) binding assay, enzyme-linked assay, and radioactivity.

3.2 Delivery and Pharmacokinetics of RNA

The issues of delivery of an exogenously made RNA drug are not much unlike those of DNA transfection and gene therapy. In cell culture, Oligofectamine (Life Technologies, Gaithersburg, MD, USA) and TransIT-TKO reagent (Mirus Corp., Madison, WI, USA) are used by many laboratories with success. Cellular permeation is also improved by conjugation with specific peptides such as helical peptides, Tat protein of HIV, and Antennapedia of *Drosophila*. In live animals, consistent delivery of sufficient quantities of RNA remains a challenge. In mice, ''hydrodynamic injection'' through the tail vein effectively delivers the RNA into hepatocytes. The optimum amount is 10 to 15% of the animal's body weight injected within 5 to 7 s. Injection of a large bolus is believed to result in short-term right heart failure and backflow of a large volume into the liver. However, hydrodynamic injection through the tail vein may not transport the RNA to all cells of the body, and is an impossible procedure in human subjects.

Once the RNA is delivered, the major issues are its pharmacokinetic properties, namely, stability in tissues and body fluids, metabolism and urinary excretion, and the potential toxicity of large amounts of RNA needed for the intended therapeutic effect. Although generally well tolerated, each RNA needs to be tested for these parameters because it may have unique effects on cellular gene expression. This

is particularly important in designing second-generation RNA drugs conjugated to novel non-RNA moieties, which results in unique conjugates that do not exist in nature. It is also to be remembered that each tissue or organ may have unique interactions with RNA. The uptake and distribution of RNA in tumor tissues are typically poor compared to normal tissues. While working with live animals and human patients, considerations must also be given to the possibility that viral vectors may cause systemic infections and immune reactions.

4 An RNA Drug for Every Disease?

In this article, we have detailed a relatively large number of recent and emerging clinical applications of various forms of RNA. Despite its phenomenal prospect, however, it should be borne in mind that RNA is a relatively new entrant in the pharmaceutical arena, and considerable work still needs to done for RNA-based drugs to become common items in the family medicine cabinet. The major areas where improvement is still desirable are as follows: cost, delivery, stability, and specificity. The first three issues have been discussed. When compared to most small molecular drugs, RNA is in fact highly specific, primarily because essentially all of its clinical applications are sequence-dependent. Double-stranded RNAs (dsRNAs) that are longer than about 35 base pairs tend to trigger the so-called ''interferon response,'' in which the dsRNA binds to and activates dsRNA-activated protein kinase, PKR. Among the many cellular proteins that are substrates of PKR, a strategically important one is the translation initiation factor, eIF2α, phosphorylation of which leads to global translational shutoff and sometimes, cell death. Primarily by virtue of their shorter length, siRNAs do not activate the IFN response, which is the key to their target-specific effect. However, siRNAs sometimes do affect off-target gene expression, especially when large amounts are applied. This is, in part, due to their ability to tolerate some degree of mismatch. The mechanism or extent of such nonspecificity and its potential impact on the clinical applications of RNA remain an area of active debate. On a practical note, it should be realized that there is no chemical or medicine that is totally free of side effects, especially when subjected to exquisitely sensitive molecular biological screening such as microarray analysis, and that the real-life issue in medicine is the balance between risk and benefit.

In principle, multiple RNA-based strategies can be applied to a given target. For example, an mRNA can be silenced by antisense RNA, ribozyme, or siRNA. Currently, there is no clear *a priori* guideline to choose one over the others, primarily because there are few studies comparing them under identical conditions. The general consensus is that siRNAs may perform as well as or better than antisense and ribozyme. One can envisage that their relative effectiveness would be influenced by a variety of factors, including tissue or cell type, transfection technique, target sequence, and chemical modification.

From an entrepreneurial perspective, the annual worldwide market for RNA-based therapy is estimated to be as high as $200 billion (US). The excitement in this area is underscored by the growing number of Biotech

companies that have added RNA-based drugs or reagents in their R&D portfolio. Some of the major names are as follows: Acuity Pharmaceuticals, Ambion, Antisense Pharma GmbH, Archemix Corporation, AVI BioPharma, Avocel, Benitec, CytRx, Dharmacon Research, Devgen, Enzo Biochem, EpiGenesis Pharmaceuticals, Genta, Hybridon, Intradigm, Imgenex Corporation, Immusol, Intronn, International Therapeutics, Intradigm, Isis Pharmaceuticals, Lorus Therapeutics, Merix Bioscience, MethylGene, Mirus Corporation, NascaCell GmbH, NeoPharm, Neucleonics, NOXXON Pharma AG, Polgen, PTC Therapeutics, Qiagen NV, Ribozyme Pharmaceuticals, Sequitur, Sirna Therapeutics, SomaGenics, and SomaLogic.

In the past few years, RNA drugs of virtually every category described here have progressed through different stages of development including clinical trials, and have produced encouraging results. Indeed, the breadth and scope of the emerging clinical applications of RNA are only matched by the diversity of the biological tasks assigned to RNA by Mother Nature. It is fair to say that the full potential of RNA as a pharmaceutical entity has only begun to be appreciated, and that RNA drugs against a variety of diseases and infections will achieve blockbuster status in the foreseeable future.

Acknowledgment

We apologize to readers and colleagues for often referring to comprehensive reviews instead of original research papers due to space limitations. Work in our laboratory was generously supported by Burroughs Wellcome Foundation, American Heart Association Southeast Affiliate (AL G970031), and NIH, USA (AI045803, EY013826, F32 AI049682, AI37938). We acknowledge Titus Barik for help in sequence analysis and other computational projects.

Keywords

Arachidonic Acid
A 20 carbon fatty acid with 4 double bonds. It is the fatty acid precursor of eicosanoids.

Diacylglycerol
An intermediate in phospholipid biosynthesis and an activator of protein kinase C.

Inositol-trisphosphate
A cyclohexane ring substituted with a hydroxyl group on each carbon and a phosphate on the hydroxyl groups of carbon number 1,4, and 5.

Phosphatidylcholine
Quantitatively the most important phospholipid found in eucaryotes.

Platelet-activating Factor
A potent compound that at a concentration of 10^{-11} M will cause platelets to aggregate and has many other biological activities.

Protein Kinase
An enzyme that phosphorylates a protein on the amino acids, serine, threonine, or tyrosine.

Second Messenger
A compound that is formed within a cell in response to a hormone or other agonists binding to a specific receptor on the cell surface.

Phospholipids are biological compounds that contain phosphorus and have both hydrophobic and hydrophilic moieties. They are ubiquitous components of all biological membranes. Phospholipids provide the basic structure and the permeability barriers of cellular membranes. The absolute requirement for phospholipids in life is underscored by the apparent lack in animals of gene mutations in phospholipid biosynthesis. Such mutations would result in severely defective enzyme activities and would probably be lethal. Phospholipids also act as sources for cellular second messengers such as diacylglycerol and inositol-trisphosphate. Phospholipids are made within each cell from precursors that include fatty acids, glycerol, CTP, ATP, and compounds that contain a free hydroxyl group such as ethanolamine, choline, glycerol, inositol, or serine. The phospholipids are made by biosynthetic enzymes and degraded by phospholipases. Many of the genes for these enzymes from *Escherichia coli*, yeast, mice, and humans have been cloned and characterized. Recent progress in the targeting of murine genes encoding several phospholipids by biosynthetic enzymes has provided insight into the function of these genes.

1 Structure of Phospholipids

The basic strucutre of all phospholipids is shown in Fig. 1. In mammals, the fatty acid attached to carbon 1 is usually saturated [palmitate (16 : 0) or stearate (18 : 0)]. In the abbreviation of fatty acids, the number to the left of the colon indicates the number of carbons and the number to the right indicates the number of double bonds. Unsaturated fatty acids [oleate (18 : 1), linoleate (18 : 2), arachidonate (20 : 4), docosahexaenoate (22 : 6)] are usually found on carbon 2. However, there are exceptions where saturated fatty acids are found on both carbons, or unsaturated fatty acids are found on both carbons. Small percentages (1 to 5%) of such phospholipids are found in most tissues. However, lung surfactant (which keeps lungs from collapsing when air is expelled) contains approximately 70% of its phosphatidylcholine (PC) as dipalmitoyl-phosphatidylcholine. The retina has as a major phospholipid species in its membrane, phosphatidylcholine that has docosahexaenoate (22 : 6) on both carbons. The function of this highly unsaturated phospholipid in the retina is unknown. The phospholipids in *E. coli* do not contain polyunsaturated fatty acids. Thus, usually a saturated fatty acid is on carbon 1 and an 18-carbon monounsaturated fatty acid (*cis*-vaccenic acid) on carbon 2.

Linked to phosphate on carbon 3 is one of the five small compounds (choline, ethanolamine, serine, glycerol, inositol) that have a hydroxyl functional group. The phospholipids are named ''phosphatidyl'' (the diacylglycerol phosphate moiety), followed by the name of the small compound such as choline (e.g. PC). A sixth phospholipid, diphosphatidylglycerol (DPG), also known as *cardiolipin*, has phosphatidylglycerol (PG) linked to the phosphatidyl moiety. There are other minor phospholipids, some of which will be mentioned later in this chapter.

In addition to the diacyl-phospholipids, there are two other classes in which the

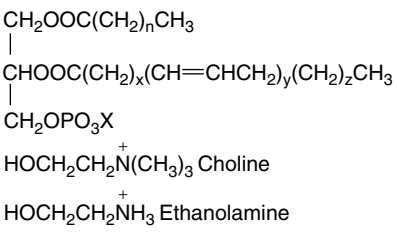

Fig. 1 General structure of a phospholipid. The *X* component can be one of five compounds that contains a hydroxyl group linked to the phosphate residue. The structures of two of these compounds is shown. Usually, there is a saturated fatty acid on carbon 1 of the glycerol moiety and an unsaturated fatty acid on carbon 2. In some cases, the substituent on carbon 1 can be a long-chain alcohol instead of a fatty acid.

acyl group on carbon 1 has been replaced by an ether linkage. If the substituent is a saturated alkyl ether, the phosphatidyl moiety is then referred to as *plasmanyl*. If the substituent is a vinyl (1,2-cis double bond) alkyl ether, the phosphatidyl moiety is referred to as *plasmenyl*. Plasmenylethanolamine is a major component of many cells and tissues such as the heart. The ether-containing phospholipids are absent from many but not all prokaryotes.

The phospholipid composition of tissues and cells is surprisingly consistent with PC and phosphatidylethanolamine (PE) being present at the highest concentrations (20 to 40% each). Phosphatidylserine (PS), phosphatidylinositol (PI), PG and DPG are each present at concentrations in the range of 10% of the total phospholipid. The subcellular membranes usually have minor differences in the phospholipid compositions with the exception of mitochondria. Phosphatidylglycerol and DPG are generally found only in this organelle along with the other phospholipids.

2 Biosynthesis of Phospholipids

2.1 Pathways

The major pathways for the biosynthesis of phospholipids in animals are shown in Fig. 2. In the first stage, fatty acids are esterified to glycerol-3-phosphate to yield phosphatidic acid (PA). The latter compound can react with cytidine triphosphate (CTP) to yield CDP-diacylglycerol (CDP-DG). In animal cells, CDP-DG reacts with inositol to form PI or with glycerol to form phosphatidylglycerol (PG). The PG then reacts with another molecule of CDP-DG to form DPG (cardiolipin). Alternatively, the phosphate of PA can be removed by the enzyme phosphatidic acid phosphohydrolase (PAP) to yield diacylglcyerol. Diacylglcyerol (DG) reacts with either CDP-choline to make PC or CDP-ethanolamine to make PE. Note that the formation of a phospholipid *de novo* always requires CTP.

Phospholipids can be modified in several ways. For example, PE (or PC) can react with serine to form PS that can be decarboxylated to PE (Fig. 2). This appears to be the only way in nature that ethanolamine is generated. The ethanolamine can then be used via the CDP-ethanolamine pathway to make PE. Hence, the CDP-ethanolamine pathway is sometimes referred to as a *salvage pathway*. In another modification, PE can be methylated to PC by three successive transfers of methyl groups from *S*-adenosylmethionine catalyzed by phosphatidylethanolamine *N*-methyltransferase (PEMT). This appears to be the major pathway by which the choline moiety of PC is made *de novo*, since

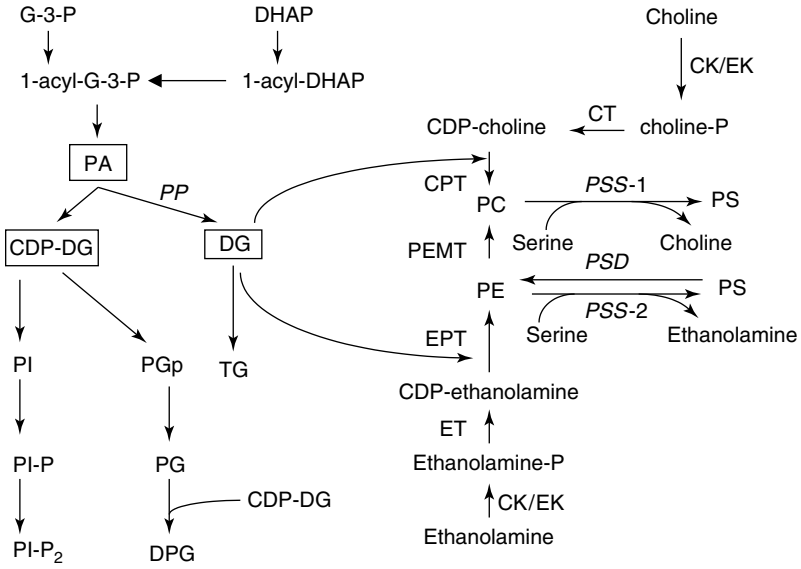

Fig. 2 Outline for the biosynthesis of the major phospholipids in human cells. The abbreviations are DHAP, dihydroxyacetone phosphate; G-3-P, glycerol-3-phosphate; PA, phosphatidic acid; DG, diacylglycerol; TG, triacylglycerol; CDP-DG, cytidine diphosphodiacylglycerol; PI, phosphatidylinositol; PG, phosphatidylglycerol; PGP, phosphatidylglycerol phosphate; DPG, diphosphatidylglycerol; PP, phosphatidic acid phosphohydrolase; PE, phosphatidylethanolamine; PC phosphatidylcholine; PEMT, phosphatidylethanolamine *N*-methyltransferase; CT, CTP: phosphocholine cytidylyltransferase; CDP-choline, cytidine diphosphocholine; choline-P, phosphocholine; CDP-ethanolamine, cytidine diphosphoethanolamine; ethanolamine P, phosphoethanolamine; PS, phosphatidylserine; CK/EK, choline kinase/ethanolamine kinase; CPT, CDP-choline:1,2-diacylglycerol cholinephosphotransferase; EPT, CDP-ethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase; ET, CTP: phosphoethanolamine cytidylyltransferase; PSD, phosphatidylserine decarboxylase; PSS, phosphatidylserine synthase.

PC can be degraded by phospholipases to yield choline, which can then be reutilized to make PC by the CDP-choline pathway. In animal tissues, the methylation pathway is abundant in the liver but present only at much lower levels in other tissues. The methylation pathway is absent in most prokaryotes, but is present in yeast. Also, though not shown in Fig. 2, the fatty acid moieties of phospholipids can be removed (deacylated) and replaced by another fatty acid (reacylated). Finally, the phosphocholine moiety of PC can be transferred to ceramide (*N*-acyl-sphingosine) to form sphingomyelin (SM). This particular phospholipid is usually found enriched in the plasma membrane of cells.

The enzymes of phospholipid biosynthesis are found in the cytosol, endoplasmic reticulum (ER), mitochondria-associated membrane (MAM, a section of the ER that sediments with mitochondria after homogenization of cells/tissues), Golgi, peroxisomes, mitochondria, and the nucleus. Only a few membrane-bound phospholipid biosynthetic enzymes from

animal sources have been purified to homogeneity. This means that purification requires solubilization of the enzymes from the membranes by detergents such as deoxycholate, Triton X-100, or others. Unfortunately, to keep the enzyme soluble it is necessary to have detergents present during the purification steps and this greatly complicates the procedures.

2.2 Enzymes of Phosphatidylcholine Biosynthesis

2.2.1 Historical Background

PC was first described by Gobley in 1847 as a component of egg yolk and named "lecithin" after the Greek equivalent for egg yolk (*lekithos*). In the 1860s, Diakonow and Strecker demonstrated that lecithin contained two fatty acids linked to glycerol and that choline was attached to the third hydroxyl by a phosphodiester linkage. The first significant advance in understanding PC biosynthesis occurred in 1932 with the discovery by Charles Best that animals had a dietary requirement for choline. In the 1950s, the CDP-choline pathway for PC biosynthesis (Fig. 3) was described by Eugene Kennedy and coworkers. A key observation was that CTP, rather than ATP, was the activating nucleotide for PC biosynthesis. CTP is required not only for PC biosynthesis but also for the *de novo* synthesis of all phospholipids (prokaryotic and eukaryotic, excluding PA, which can

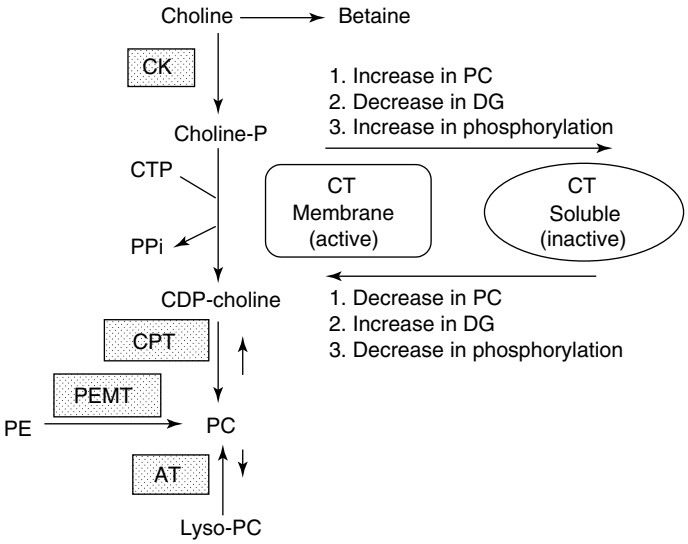

Fig. 3 Regulation of phosphatidylcholine (PC) biosynthesis via the CDP-choline pathway by modulation of the binding of CTP:phosphocholine cytidylyltransferase (CT) to membranes. Three different modes of regulation of CT activity are shown. Thus, a decrease in the concentration of PC will promote the translocation and activation of CT. An increase in PC will cause CT to be released from the membranes into a soluble, inactive form. The abbreviations are CK, choline kinase; CPT, CDP-choline: 1,2-diacylglycerol cholinephosphotransferase; PEMT, phosphatidylethanolamine *N*-methyltransferase; AT, lyso-PC acyltransferase; PE, phosphatidylethanolamine; DG, diacylglycerol.

be considered to be an intermediate in glycerolipid biosynthesis).

An alternative pathway for PC biosynthesis, of quantitative significance only in liver, is the conversion of PE to PC via PE methylation (Fig. 2). The first observation of this pathway was in 1941 when Stetten fed [^{15}N]ethanolamine to rats and isolated [^{15}N]choline. Two decades later, Bremer and Greenberg detected a microsomal enzyme that converted PE to PC via transfer of methyl groups from *S*-adenosylmethionine.

2.2.2 Choline Transport and Oxidation

Choline is not made *de novo* in animal cells except by methylation of PE to PC and subsequent hydrolysis of the choline moiety. Therefore, choline must be imported from extracellular sources. There are two distinct transport mechanisms for choline: a high affinity (K_m or $K_t < 5\,\mu M$), Na-dependent transporter and a lower affinity ($K_t > 30\,\mu M$), Na-independent transporter. Several cDNAs encoding proteins that show high affinity transport of choline have been reported. A human cDNA is predicted to have 13 transmembrane-spanning domains.

Once choline is inside the cell, its normal fate is rapid phosphorylation by choline kinase (Fig. 3). In neurons, choline is also converted to the neurotransmitter, acetylcholine. Choline is also oxidized to betaine [$^{-}$00C-CH$_2$-N^{+} (CH$_3$)$_3$] in the liver and kidney. In the liver, betaine is an important donor of methyl groups for methionine biosynthesis and the one carbon pool. Betaine is produced in mitochondria into which choline is transported by a specific transporter on the inner membrane. Next, choline is oxidized to betaine aldehyde by choline dehydrogenase on the inner leaflet of the inner mitochondrial membrane. The conversion to betaine is catalyzed by betaine-aldehyde dehydrogenase located in the mitochondrial matrix. In the renal medulla, betaine accumulates as an osmolyte (a small organic solute that accumulates in response to hypertonicity without adverse affect to the cell or organism). Hypertonicity of the renal medulla is important for the kidney's ability to concentrate urine.

2.2.3 Choline Kinase

The enzyme was first demonstrated in yeast extracts by J. Wittenberg and A. Kornberg (more famous for his contributions to DNA replication) in 1953. The enzyme was purified by K. Ishidate in 1984 from rat kidney and shown also to phosphorylate ethanolamine. This kinase is now referred to as *choline/ethanolamine kinase ß*. The cDNA for a rat liver choline/ethanolamine kinase encoded an enzyme that is now referred to as *choline/ethanolamine kinase* α1. Northern analyses indicate that the mRNA for choline/ethanolamine kinase α1 is most abundant in testis. Choline/ethanolamine kinase α2 appears to be a splice variant of choline/ethanolamine kinase α1. The choline/ethanolamine kinase α and ß genes have been characterized. The length of the gene was 40 kb for the choline/ethanolamine kinase α gene, whereas the ß gene was only 3.5 kb in length.

Choline is not only required in the diet of animals but also in the medium of animal cells in culture. Choline is essential because of the cell's requirement for PC to grow and divide.

2.2.4 CTP:Phosphocholine Cytidylytransferase (CT)

This enzyme was first described by Kennedy and Weiss in 1955. Over three

decades later, cytidylytransferase (CT) was finally purified to homogeneity. The CT gene was cloned from *Saccharomyces cerevisiae* by S. Yamashita in 1987 by complementation of a yeast mutant defective in CT activity. The cDNA of rat liver CT was subsequently cloned by R.B. Cornell and coworkers in 1990. CT is a homodimer in soluble extracts of rat liver and is also found on membranes. In most cells, CT is thought to exist in an inactive reservoir in its soluble form and to be activated when associated with membranes (Fig. 3).

Two genes encode different forms of CT: α and ß. The *CTα* gene spans approximately 26 kb. Exon 1 is untranslated, exon 2 encodes the translation start site and a nuclear localization signal, exons 4–7 encode the catalytic domain, exon 8 codes for the alpha helical membrane–binding domain, and exon 9 encodes a C-terminal phosphorylation domain.

The *CTß* gene is located on the X chromosome and encodes three isoforms, CTß1, CTß2, and CTß3 (Fig. 4), presumably derived by mRNA splicing. Presently CTß1 has only been found in humans. All isoforms differ from CTα at the amino terminus, lack the nuclear localization signal, and are found in the cytoplasm of animal cells. The primary sequences of CTß1and CTß2 are identical except at the carboxyl terminal. CTß1 lacks most of the phosphorylation domain that is present in CTß2. There are significant differences between the sequences of the phosphorylation domains of CTα and CTß.

CT has classically been considered to be a cytoplasmic enzyme since its activity is found in the cytosol and on microsomal membranes in cellular homogenates. However, Kent and coworkers demonstrated that CT was found in the nuclear matrix and associated with the nuclear membrane. There is intriguing evidence that CTα migrates into the cytoplasm during the G1 phase of the cell cycle, a time when PC biosynthesis is activated. Thus, the role the nuclear localization signal of CT plays in cellular PC biosynthesis remains an intriguing question.

The lipid-binding domain and the phosphorylated domains are involved in the regulation of CT activity. These domains

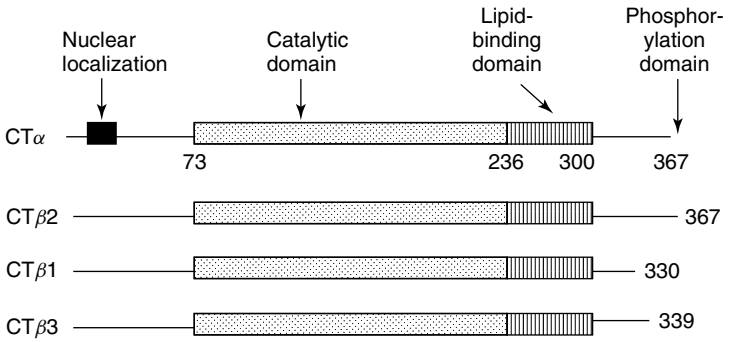

Fig. 4 Domain structures of CTP:phosphocholine cytidylyltransferase (CT) α, ß1, ß2, and ß3. CTα contains a nuclear localization signal, an N-terminal catalytic domain, an amphipathic helical (lipid-binding) domain, and a C-terminal phosphorylation domain. The CT ß forms lack the nuclear localization signal but contain catalytic and amphipathic helical domains. CT ß1 is missing the phosphorylation domain, whereas CTß2 and CTß3 have a phosphorylation domain that is different from that of CTα.

of CTα have been deleted by either proteolysis with chymotrypsin or by construction of CTα truncation mutants. CTα cDNAs that were truncated in the region of residue 314 (Fig. 4) lacked the phosphorylation segment, and CT truncated at residues 236, 231, or 228 lacked both the phosphorylation and lipid-binding domains. When the lipid-binding and phosphorylation domains were deleted, CT was a soluble, active enzyme that did not bind to membranes. Thus, the lipid-binding domain is regulatory for the binding to membranes and the activation of CT. The binding of phospholipids to CT appears to activate the enzyme by decreasing the apparent K_m value for CTP.

CT activity is modulated by phosphorylation. Experiments with CT truncation mutants have demonstrated that the phosphorylation domain is not required for lipid-binding or CT activity. Exactly what role phosphorylation of CT plays in a physiologically relevant system remains to be demonstrated.

2.2.5 CDP-choline: 1,2-diacylglycerol Cholinephosphotransferase

This enzyme was also discovered by Kennedy and coworkers and is considered to be located on the ER but is also found on the Golgi, MAM, and nuclear membranes. Even though the enzyme has been known for more than four decades, despite intense efforts in many laboratories, the cholinephosphotransferase has never been purified. The difficulty is that the enzyme is an intrinsic membrane-bound protein that requires detergents for solubilization. Moreover, the detergents complicate purification procedures commonly used, such as gel filtration, because the protein binds to micelles that are hard to separate on the basis of molecular size. The purification of membrane-bound enzymes has been described as ''masochistic enzymology''.

Yeast genetics and molecular biology have, however, allowed for the cholinephosphotransferase to be cloned. The products of two genes, *CPT1* and *EPT1*, each account for 50% of the cholinephosphotransferase activity in yeast extracts. By the use of null mutations in these two genes, it has been established that *CPT1* is responsible for 95% of the PC made and the *EPT1* gene product accounts for 5%. The *EPT1* gene product utilizes both CDP-choline and CDP-ethanolamine, whereas *CPT1* catalyzes only reactions with CDP-choline.

More recently, a human choline/ethanolamine-phophotransferase cDNA (hCE PT1) was cloned and expressed, and an additional human cDNA was cloned that encoded a CDP-choline-specific enzyme (hCPT1) with 60% sequence identity to hCEPT1.

Cholinephosphotransferase acts at a branch point in the metabolism of DG that can also be converted to PE, triacylglycerol (TG) or PA (Fig. 2). Most studies indicate that there is an excess of cholinephosphotransferase in cells; hence, the amount of active enzyme does not limit PC biosynthesis. However, it is clear that the *in vivo* activity of cholinephosphotransferase is regulated by substrate supply. The supply of CDP-choline is regulated by the activity of CT. The supply of DG in the liver seems to be controlled by the supply of fatty acids. The excess DG that is not utilized for PC or PE biosynthesis is stored in the liver as TG.

2.2.6 Phosphatidylethanolamine *N*-methyltransferase

All nucleated cells contain PC and the CDP-choline pathway. Thus, it was not

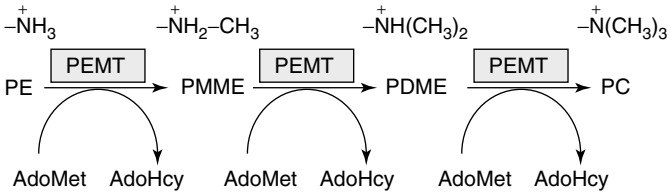

Fig. 5 Reactions catalyzed by PEMT, phosphatidylethanolamine *N*-methyltransferse; PE, phosphatidylethanolamine; AdoMet, *S*-adenosylmethionine; AdoHcy, *S*-adenosylhomocysteine; PMME, phosphatidylmonomethylethanolamine; PDME, phosphatidyldimethylethanolamine; and PC, phosphatidylcholine.

obvious why the pathway for PE methylation (Fig. 5) survived during evolution. Nor was it obvious why PEMT activity is mostly found in the liver, whereas 2% or less of the hepatic PEMT activity is found in other tissues of the body.

PEMT was purified from rat liver microsomes although it is an intrinsic membrane protein. The sequencing of the amino terminal enabled the cloning of the cDNA for PEMT. Preparation of an antibody to the deduced sequence of the carboxyl terminal peptide permitted subcellular localization of the enzyme. The major activity for PEMT is found on the ER, but the antibody only recognizes a protein that is exclusively localized to MAM. This isoenzyme of PEMT is referred to as PEMT2 and the activity on the ER is called PEMT1. Both PEMTs catalyze all three transmethylation reactions that convert PE to PC (Fig. 5).

A mouse was generated in which the *Pemt* gene was disrupted and there was no PEMT activity. The $Pemt^{-/-}$ mice lived and bred normally and there was a 50% increase in CT activity in their livers. Since the mice retained the CDP-choline pathway, the lack of an obvious phenotype was not surprising. However, when the mice were fed a choline-deficient diet for 3 days, which attenuates PC synthesis via the CDP-choline pathway, the $Pemt^{-/-}$ mice exhibited severe liver failure. $Pemt^{+/+}$ mice fed a choline-deficient diet were normal with no obvious liver pathology. Thus, it seems that the PEMT pathway has survived in evolution to provide PC at times when the CDP-choline pathway is less active such as might occur during starvation. Moreover, pregnant rats and suckling mothers can also have choline reserves depleted; hence, the PEMT pathway might provide an evolutionary advantage in this respect. The structurally related compound, dimethylethanolamine [$H0CH_2$-CH_2-N^+ $H(CH_3)_2$] would not substitute for choline in the $Pemt^{-/-}$ mice even though it was converted to phosphatidyldimethylethanolamine. Thus, it seems that the third methyl group on the phospholipid has a critical function in mice.

The human gene-encoding PEMT has been cloned and characterized. Whereas only one mRNA transcript has been identified in mice, the human liver has three separate mRNAs that differ only at the 5′ end, in a noncoding region of the transcript. Thus, the three transcripts encode the same protein. The function of separate PEMT mRNAs is going to be difficult to study in humans.

Yeast also has both the PE methylation pathway and the CDP-choline pathway. In

yeast, two enzymes are used for the conversion of PE to PC. The methylation of PE to phosphatidylmonomethylethanolamine is catalyzed by the *PEM1*/*CHO2* gene product, whereas the subsequent two methylations are catalyzed by the *PEM2*/*OPI3* gene product. Deletion of both *PEM1* and *PEM2* genes is lethal unless the yeast is supplied with choline. Yeast normally grows in the absence of choline and depends on the PEMT pathway. Thus, the CDP-choline pathway and the PE methylation pathway can compensate for each other in yeast.

2.2.7 Phosphatidylcholine in Bacteria

About 90% of bacteria do not contain PC but *Rhodobacter sphaeroides* make PC by methylation of PE. Interestingly, this enzyme (PC) is soluble and has virtually no homology to PEMT or the yeast enzymes. Also, in one bacterium, a novel choline-dependent pathway was recently discovered in *Sinorhizobium meliloti*, in which choline reacts with CDP-diacylglycerol, catalyzed by PC synthase, to form PC. A number of symbiotic bacteria and pathogenic bacteria also produce PC via the same PC synthase pathway.

2.3 Enzymes of Phosphatidylethanolamine Biosynthesis

2.3.1 Historical Background

PE was first alluded to in a book published by Thudichum in 1884. He described ''kephalin'' as a nitrogen- and phosphorus-containing lipid that was different from lecithin. In 1913, Renall and Baumann independently isolated ethanolamine from kephalin. In 1930, Rudy and Page isolated the first pure preparation of PE. The structure of PE was established in 1952 by Baer and colleagues.

The biosynthesis of PE in eukaryotes can occur via four pathways (Fig. 6). The route via CDP-ethanolamine constitutes *de novo* synthesis of PE. The other pathways arise as a result of the modification of a preexisting phospholipid. The CDP-ethanolamine pathway was first described by Kennedy and Weiss in 1956. The decarboxylation of PS to yield PE (Fig. 6) was shown in 1960 to occur in animal cells. PS decarboxylation is the only route for PE biosynthesis in *E. coli*. The PE generated by this pathway can react with serine to generate PS and ethanolamine (Fig. 6). This appears to be one mechanism by which ethanolamine is made in cells. The other involves degradation of sphingosine. The ethanolamine generated by either pathway can be utilized for PE biosynthesis via the CDP-ethanolamine pathway. No one has ever been able to show the decarboxylation of serine to ethanolamine in animal cells. Such a reaction was shown to occur in a plant, *Arabidopsis thaliana*. PE can also be formed by reacylation of lyso-PE or reaction of ethanolamine with PS (Fig. 6).

2.3.2 Enzymes of the CDP-ethanolamine Pathway

As mentioned in Sect. 2.2.3, the phosphorylation of ethanolamine in liver can be catalyzed by choline/ethanolamine kinase (Fig. 6). The cDNA encoding an ethanolamine kinase was cloned from *Drosophila*. These scientists had not planned on cloning this cDNA since their approach was to determine the gene responsible for the easily shocked (*eas*) phenotype in this insect. These mutant flies display transient paralysis following a brief mechanical shock. In the *eas* mutant, a 2-bp deletion caused the formation of a premature stop codon in the ethanolamine kinase gene. Analysis of the phospholipids

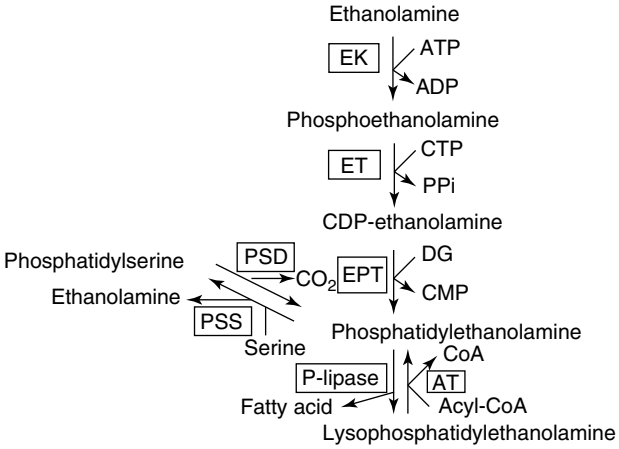

Fig. 6 Pathway for biosynthesis of phosphatidylethanolamine and phosphatidylserine in animal cells. The abbreviations are EK, ethanolamine(choline) kinase; ET, CTP: phosphoethanolamine cytidylyltransferase; EPT, CDP-ethanolamine: 1,2-diacylglycerol ethanolaminephosphotransferase; PSS, phosphatidylserine synthase; PSD, phosphatidylserine decarboxylase; P-lipase, phospholipase A_2; AT, acyl-CoA: lyso-phosphatidylethanolamine acyltransferase; DG, diacylglycerol.

showed a decrease in PE from 59% of the total phospholipid in the wild type to 56% in *eas*. Whether this minor change mediates the paralysis is not known. The difference may reflect a major change in PE content in a particular tissue or subcellular membrane. More recently, the gene that encodes a yeast ethanolamine kinase and a human cDNA for ethanolamine-specific kinase were cloned and expressed.

The second step in the CDP-ethanolamine pathway is catalyzed by CTP:phosphoethanolamine cytidylyltransferase. The enzyme is distinct from CT and is not activated by lipids. Although the phosphoethanolamine cytidylyltransferase is recovered in cytosol from cell extracts, much of the enzyme has been localized to rough ER of rat liver by immunoelectron microscopy. Unlike CTα, there is no report of the phosphoethanolamine cytidylyltransferase in the nucleus.

CDP-ethanolamine: 1,2-diacylglycerol ethanolaminephosphotransferase is an integral membrane protein found on the ER, Golgi, and MAM. The enzyme shows a distinct preference for DG species that contain 1-palmitoyl-2-docosahexaenoyl (22 : 6) fatty acids. In hepatocytes in culture, nearly 50% of PE made via the ethanolaminephosphotransferase reaction belongs to this species. The purpose of this extraordinary selectivity is unknown. The bovine hepatic enzyme was purified, and exhibited both ethanolamine- and cholinephosphotransferase activity.

2.4 Phosphatidylserine Synthase and Decarboxylase

2.4.1 Historical Developments and Biosynthesis

PS accounts for 5 to 15% of the phospholipids in eukaryotic cells. The lower

concentration of PS compared to PC and PE is probably the reason PS was not discovered as a separate component of "kephaline" (originally identified to be only PE in 1930) until 1941 by Folch. The correct structure was proposed by Folch in 1948 and confirmed by chemical synthesis in 1955 by Baer and Maurukas. PS is a required cofactor for protein kinase C and is required for initiation of the blood-clotting cascade. In the plasma membrane of cells, PS is normally located on the inner monolayer. During apoptosis, exposure of PS on the cell surface (outer monolayer) leads to recognition and removal of these cells by macrophages.

PS is made in prokaryotes, in some plants and in yeast via the CDP-diacylglycerol pathway. This route does not exist in animals. Instead, PS is made by a base-exchange reaction catalyzed by PS synthase, first described by Hübscher in 1959, in which the head group of PC or PE is exchanged for serine.

Chinese hamster ovary (CHO) mutants were generated that were auxotrophic for PS and demonstrated that these cells have two PS synthases. PS synthase 1 utilizes PC and serine as substrates, whereas PS synthase 2 utilizes only serine and PE. The two PS synthases, when coupled with PS decarboxylase, yield PS at the expense of PC and generate both choline and ethanolamine, which could be recycled into the biosynthesis of PC and PE. As a result, PS and PE can both be generated without a decline in the amount of PC.

PS synthase 1

$$\text{PC} + \text{serine} \longrightarrow \text{PS} + \text{choline}$$

PS decarboxylase

$$\text{PS} \longrightarrow \text{PE} + \text{C0}_2$$

PS synthase 2

$$\text{PE} + \text{serine} \longrightarrow \text{PS} + \text{ethanolamine}$$

The sum of the reactions is

$$\text{PC} + \text{two serines} \longrightarrow \text{PS} + \text{choline} + \text{ethanolamine} + \text{CO}_2$$

A CHO mutant defective in PS synthase 1 was used to clone by complementation of the cDNA for this enzyme. The deduced amino acid sequence for murine PS synthase 1 was >90% identical to the CHO enzyme. The cDNA for PS synthase 2 from CHO cells was cloned and shown to be 32% identical in amino acid sequence to PS synthase 1. Immunoblot analysis indicated that both of the murine PS synthases are mainly localized to MAM. The source of the substantial PS synthase activity in the rough and smooth ER remains unknown and may possibly be a third PS synthase activity. The mRNAs encoding PS synthases 1 and 2 were found in all murine tissues examined, but PS synthase 2 was enriched in testis and kidney.

The murine gene for PS synthase 1 has been cloned and characterized. This is an important step toward the generation of mice with a disrupted gene for PS synthase 1. The gene for PS synthase 2 has been disrupted and the mice are viable.

In yeast and in *E. coli*, PS is made by a different reaction than in mammals. In these organisms, CDP-diacylglycerol condenses with serine to yield cytidine mono phosphate (CMP) plus PS.

2.4.2 Phosphatidylserine Decarboxylase

PS decarboxylase is found in both prokaryotes and the mitochondria of eukaryotes. The enzyme activity was first described by Kanfer and Kennedy in 1964. The enzyme has not been purified from a

eukaryotic source but the gene was cloned and expressed from CHO cells and yeast. The yeast gene (*PSD1*) encodes a protein that is localized to mitochondria. However, when *PSD1* was disrupted in yeast, 5% PS decarboxylase activity remained and the yeast continued to grow. Subsequently, a second gene, *PSD2*, was isolated. When both *PSD1* and *PSD2* were disrupted, the yeast became ethanolamine auxotrophs. The PSD2 protein has been localized to the vacuolar and Golgi compartments. The function of *PSD2* is not known other than that it can supply enough PS decarboxylase to allow growth of yeast in the absence of *PSD1*. The rate of PS decarboxylation is determined by the rate of PS transport into mitochondria.

2.5 Bis(monoacylglycerol)phosphate, Phosphatidylglycerol, and Diphosphatidylglycerol

Diphosphatidylglycerol (DPG), commonly known as cardiolipin, was discovered in 1942 in beef heart by Pangborn. The correct structure was proposed in 1956–1957 and confirmed by chemical synthesis in 1965–1966 by de Haas and van Deenen. Phosphatidylglycerol was first isolated in 1958 from algae by Benson and Mauro. The structure was confirmed by Haverkate and van Deenen in 1964–1965. The third lipid in this class, bis(monoacylglycerol)phosphate was recovered from pig lung by Body and Gray in 1967. The stereochemistry differs from PG and DPG since bis(monoacylglycerol)phosphate contains *sn*-(monoacyl)glycerol-1-phospho-*sn*-1′-(monoacyl)-glycerol rather than a *sn*-glycerol-3-phospho linkage.

These three lipids are widely distributed in animals, plants, and microorganisms. In animals, DPG is found in highest concentration in the cardiac muscle (9–15% of phospholipid), hence the name cardiolipin, and is exclusively found in the mitochondria. PG is generally present at a concentration of less than 1% of total cellular phospholipids, except in the lung, where it comprises 2 to 5% of the phospholipid. In pulmonary surfactant and alveolar type II cells, PG is 7 to 11% of the total lipid phosphorus. Bis(monoacylglycerol)phosphate comprises less than 1% of total phospholipids in animal tissues, except in alveolar (lung) macrophages, where it is 14 to 18% of the total phospholipid.

The biosynthesis of PG was elucidated by Kennedy and coworkers in 1963 (Fig. 2). For DPG biosynthesis, PA is transferred from CDP-DG to PG to yield DPG. DPG synthesis in *E. coli* differs and involves the condensation of two molecules of PG.

Understanding the biosynthesis of bis(monoacylglycerol)phosphate has been a particular challenge because the carbon linked to the phosphate residue is the sn-1 rather than the sn-3 configuration. An intermediate in the biosynthesis of bis(monoacylglycerol)phosphate is 1-acyl-lyso-PG, also known as *lysobis-PA*. Recent studies have shown that the inner membranes of late endosomes are enriched in lysobis-PA and that these membranes play an important role in the sorting of insulin growth factor receptor 2 and the mannose-6-phosphate receptor. Moreover, lysobis-PA cross-reacts with antibodies produced in patients with an antiphospholipid syndrome. Possibly, some of the pathological defects in this disease could arise from disruption of endosomal traffic.

PG can be made in mitochondria and microsomes from various animal cells and, except for lung, appears to be primarily

converted to DPG. DPG is biosynthesized exclusively on the matrix side of the mitochondrial inner membrane and is found only in this organelle. There is evidence that the rate-limiting step in DPG biosynthesis is the conversion of PA into CDP-DG. Consistent with this idea, the levels of CTP have been shown to regulate DPG biosynthesis in cardiac myoblasts.

Using techniques developed by Raetz and coworkers, M. Nishijima and coworkers isolated a temperature-sensitive mutant in PG-P synthase of CHO cells. The mutant had 1% of wild-type CHO PG-P synthase activity at 40 °C and a temperature-sensitive defect in PG and DPG biosynthesis. This mutant was used to show that DPG is required for the NADH-ubiquinone reductase (complex I) activity of the respiratory chain.

In yeast, DPG synthesis has been genetically disrupted. The yeast grows at temperatures between 16 and 30 °C without DPG but fails to grow at 37 °C on fermentable carbon sources such as glucose, even though intact mitochondria are, therefore, not required for ATP synthesis. Thus, mitochondria must have some necessary function in yeast survival other than generating energy.

The fatty acyl content of phospholipids can also impact on mitochondrial function. Incubation of cardiomyocytes with palmitic acid increased the palmitic acid content of PA and PG, and decreased DPG levels in mitochondria with a concomitant release of cytochrome c, leading to apoptosis.

Phosphatidylglycerolphosphate synthase has been purified from *E. coli* and the cDNA cloned. The phosphate group is cleaved from phosphatidylglycerolphosphate by a phosphatase. Genetic manipulations have demonstrated that the gene-encoding phosphatidylglycerophosphate synthase is essential for *E. Coli*. This is in contrast to PS decarboxylase, which is apparently not essential in *E. coli*. That is, these organisms seem to grow without significant amounts of the PS decarboxylase product, PE.

Cardiolipin (DPG) synthase from *E. coli* has also been purified and the cDNA cloned. This enzyme is also not an essential enzyme. An alternative pathway or enzyme seems to provide the small amount of cardiolipin that is required for growth of *E. coli*.

2.6 Phosphatidylinositol Biosynthesis and Phosphorylation

2.6.1 Historical Developments

A major outcome of PA is conversion to DG that is metabolized to PC, PE, and TG (Fig. 2). Alternatively, PA can react with CTP to form CDP-DG that is utilized for the biosynthesis of the inositol phospholipids, PG and diphosphatidylglycerol (Fig. 2).

Inositol is a cyclohexane derivative in which all 6 carbons are substituted with hydroxyl groups. The most common isoform is *myo*-inositol, but other less-abundant inositols with different structures also occur. The first report of an inositol-containing lipid was in 1930 from *Mycobacteria*, which is ironic since inositol lipids are rarely found in bacteria. Brain is the richest source of these lipids, as first discovered by Folch and Wooley in 1942. In 1949, Folch described PI phosphate (PI-P), which was later found to include PI and PI bisphosphate (PI-P_2). The chemical structures of PI, PI-P, and PI-P_2 were determined by Ballou and coworkers between 1959 and 1961. PI (1.7μmol/g liver) constitutes around 10% of the phospholipids in a cell

or tissue. PI-P and PI-P_2 are present at much lower concentrations (1–3% of PI). Agranoff et al. published the first experiments in 1958 on the incorporation of [^{3}H]inositol into PI. Subsequently, Paulus and Kennedy showed that CTP was the preferred nucleotide donor.

2.6.2 CDP-diacylglycerol Synthase

Regulation of the conversion of PA to CDP-DG is not well understood. The enzyme, CDP-DG synthase, is largely microsomal, but is also found in the mitochondrial inner membrane.

A cDNA-encoding CDP-DG synthase 1 was cloned from *Drosophila*. This isoform is specifically located in photoreceptor cells of *Drosophila*. Mutations in this isoform lead to a defect in PI-P_2 biosynthesis. As a result, mutant photoreceptor cells show severe defects in their phospholipase C-mediated signal transduction that can be rescued by reintroduction of the CDP-DG synthase cDNA.

cDNAs encoding human and murine CDP-DG synthases 1 and 2 have recently been cloned. CDP-DG synthase 2 is expressed during embryogenesis in the central nervous system, whereas CDP-DG synthase 1 has a high level of expression in the adult retina.

Curiously, in *S. cerevisiae*, CDP-DG synthase activity is found in microsomes and the mitochondrial inner membrane, even though only one gene encodes this activity. Since only a single mRNA species was found, there may not be alternative splicing of the yeast gene. The yeast CDP-DG synthase gene is essential for cell viability as well as germination of spores.

2.6.3 Phosphatidylinositol Synthase

Three potential sources for cellular inositol are diet, *de novo* biosynthesis, and recycling of inositol. Biosynthesis of inositol from glucose occurs in the brain and testes, and in other tissues to a lesser extent. The rate-limiting step appears to be the synthesis of inositol-3-phosphate from glucose-6-phosphate. Inositol-3-phosphate is hydrolyzed to inositol by a phosphatase.

PI synthase was purifed from human placenta. When the cDNAs encoding either CDP-DG synthase 1 or phosphatidylinositol synthase, or both, were overexpressed in COS 7 cells, there was no change in the rate of PI biosynthesis, indicating that the level of these enzymes was not limiting for PI biosynthesis. Disruption of the PI synthase gene in yeast is lethal, indicating that PI is essential.

PI-4,5-P_2 is an important source of the second messengers, inositol-1,4,5-P_3 and DG. The biosynthesis of PI-P_2 begins with the reaction of CDP-DG and inositol to form PI. The phosphorylation of PI on the 4 position appears to be catalyzed by several different isoenzymes. One has been purified to homogeneity with a molecular weight of 55 000 and is specific for PI on the 4 position of the inositol moiety. A second kinase with a molecular mass of approximately 200 kDa has also been partially purified. The role of the different isoenzymes of PI-4 kinase remains to be elucidated.

The next enzyme in the sequence is PI-4P kinase. There appear to be three distinct forms of this enzyme in bovine brain, and one with a molecular mass of 53 kDa has been purified to homogeneity from brain and from human red cells. A different form has also been purified from erythrocytes. A major difficulty with the purification of these PI kinases from cells is that they are not abundant enzymes in extracts.

Another derivative of PI, PI-3P, appears to be involved in a signaling pathway that is distinct from the metabolism of

PI-4,5-P_2. The purifed bovine brain PI-3 kinase is composed of an 85 and a 110-kDa subunit. The 85-kDa subunit lacks PI-3 kinase activity and appears to mediate the coupling of the 110-kDa subunit with protein tyrosine kinases that phosphorylate PI-3 kinase. The 110-kDa subunit has been cloned and shows PI-3 kinase activity when associated with the 85-kDa subunit. The 110-kDa subunit has been shown to be encoded by the *VPS*34 gene in yeast and is essential for protein sorting to the lysosome-like vacuole in yeast. Exactly how PI-3P is involved in protein sorting remains to be determined.

2.7 Remodeling of the Acyl Substituents of Phospholipids

Phospholipids are made *de novo* with the fatty acid compositions present in the precursors DG and CDP-DG. Once the phospholipid is made, the fatty acid substitutents can be remodeled via deacylation–reacylation reactions (Fig. 7). Remodeling can occur on either the sn-1 or the sn-2 positions of the glycerolipid. For example, a major molecular species formed from the conversion of PE to PC is 16 : 0–22 : 6-PC. This species of PC has a half-life of less than 6 h and appears not to be significantly degraded but rather converted to other molecular species, particularly those with 18 : 0 on the sn-1 position and 20 : 4, 18 : 2, or 22 : 6 on the sn-2 position. Other studies have suggested that the main products of *de novo* PC and PE biosynthesis are 16 : 0–18 : 2, 16 : 0–18 : 1, 16 : 0–22 : 6, and 18 : 1–18 : 2. The major remodeled product is 18 : 0–20 : 4 for both PC and PE. Why 18 : 0–20 : 4-PC and -PE are made by this circuitous route, rather than directly, is not known.

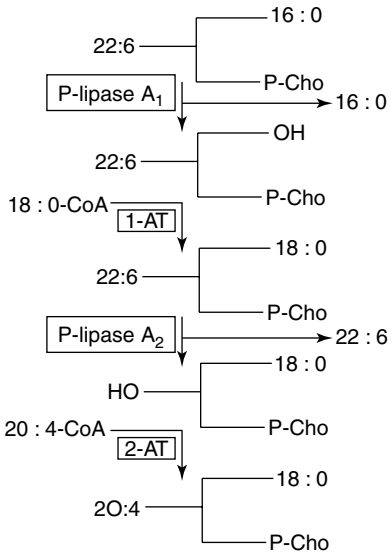

Fig. 7 One pathway by which phospholid molecular species are remodeled to change the fatty acid composition. P-lipase, phospholipase; AT, acyl-CoA: lyso-phosphatidylcholine acyltransferase; cho, choline.

2.8 Regulation of Phosphatidylcholine Biosynthesis

Of all the phospholipids, the regulation of PC biosynthesis is best understood. Generally, the activity of CTP:phosphocholine cytidylyltransferase (CT in Fig. 3) is rate-limiting and regulated. Considerable evidence has demonstrated that the rate of the CT reaction can limit PC biosynthesis. The first evidence in favor of this conclusion was the measurement of pool sizes of the aqueous precursors by Sundler and Åkesson (in rat liver choline = 0.23 mM, phosphocholine = 1.3 mM, CDP-choline = 0.03 mM). The concentration of phosphocholine is approximately 40-fold higher than

CDP-choline. The accumulation of phosphocholine is consistent with a bottleneck in the pathway at the reaction catalyzed by CT. Pulse-chase experiments with ^{3}H-choline demonstrate the bottleneck more vividly. After incubating cells with labeled choline for a short period, for example, 15 min, the cells are then ''chased'' (incubated with unlabeled choline for various durations) and the incorporation of radioactivity into PC and its precursors is measured. At the end of the pulse, approximately 90% of the radioactivity is in phosphocholine (Fig. 8). Over the next few hours, the radioactivity disappears from phosphocholine and appears quantitatively in PC. There is only a small amount of label in CDP-choline, consistent with the rapid formation of PC from CDP-choline.

Cytidylyltransferase (CT) exists as a dimer of identical subunits in the cytosol of cell homogenates where it is inactive. CT is activated by translocation of the enzyme to membranes (primarily the ER and nuclear membrane in liver) as shown in Fig. 3. The binding to the membranes appears to be via an amphipathic helix (the helix is composed of amino acids that results in a hydrophobic and hydrophilic side). Deletion of this amphipathic helix by construction of carboxyl truncation mutants of CT resulted in a protein that was active but would no longer bind to membrane lipids. The binding to the lipids in the ER activates the enzyme, at least in part, by lowering the apparent K_m for CTP. Binding of CT to membranes begins by electrostatic adsorption, followed by hydrophobic interactions that involve intercalation of the protein into the nonpolar core of the membrane. When insertion of CT into the membrane lipids is blocked by using viscous gel–phase lipids, CT binds electrostatically to the membrane, but is not activated. Four properties of membranes promote CT insertion: (1) interfacial packing defects as might occur when lipids with small head groups such as DG are in the membrane; (2) low lateral surface pressure (loose packing) as observed in highly curved compared to planar bilayers; (3) acyl chain disorder that can be caused by oxidation of the fatty acyl chains; and (4) curvature strain that would occur when

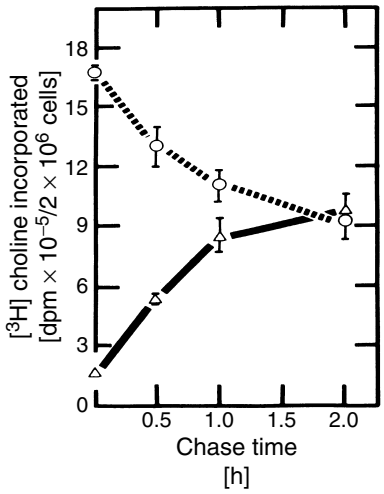

Fig. 8 Incorporation of [^{3}H-*methyl*]choline into phosphocholine and PC as a function of time. Hepatocytes from rat liver were incubated with labeled choline for 30 min. Subsequently, the cells were washed thoroughly and incubated (chased) for various times with unlabeled choline. The disappearance of radioactivity from phosphocholine (dashed line) and its appearance in PC (solid line) are shown.

membranes are enriched in hexagonal phase-preferring lipids such as PE and DG. Synthesis of PC would reverse these properties of membranes and form a more stable bilayer.

Understanding the regulation of CT activity is complicated by the observation that the enzyme is highly phosphorylated in the cytosol (potentially 16 different serine residues) and much less phosphorylated when bound to the ER. The phosphate residues are located in the carboxyl domain (residues 315 to 367) of CTα. The function of the phosphorylation of CT is being actively investigated at the present time. Experiments with mutagenesis (serine to alanine) of CT or construction of truncated forms of CT demonstrated that the phosphorylation domain of CT is not required for lipid-binding or CT activity. Recent evidence has shown that CT appears to bind to the membrane in response to a change in the lipid composition and is subsequently dephosphorylated. Thus, a change in the lipid composition of a membrane may be of primary importance compared to phosphorylation in regulating CT translocation. However, there is other evidence in studies with macrophages that dephosphorylation of CT may regulate how active CT is on the membranes.

Regulation of a metabolic pathway by product inhibition has been commonly observed. In livers or hepatocytes derived from choline-deficient rats, the rate of PC biosynthesis was inhibited by approximately 70% compared to choline-supplemented rats and there was a corresponding increased binding of CT to cellular membranes. The CT appeared to recognize a need for increased PC biosynthesis and was sitting poised on the membrane prepared for catalysis. However, because of a lack of substrate (phosphocholine), the amount of PC made was insufficient. When choline was supplied to hepatocytes under this condition, there was a nearly positive correlation between the increase in the level of PC in these cells and the release of CT into the cytosol. Similar correlations were observed when the level of PC was increased by providing methionine for enhanced conversion of PE to PC, or by providing lyso-PC, which is taken into hepatocytes and acylated to PC. This was the first study in which a mechanism for regulation of PC in cell cultures could be directly related to a physiologically relevant animal model.

An elegant feedback regulation of CT has been shown in the yeast *S. cerevisiae*. SEC14p is a phospholipid transfer protein that when assayed *in vitro* prefers PI and PC and is an essential gene product. SEC14p inhibited the CDP-choline pathway when PC was bound to SEC14p. In contrast, when PI was bound to SEC14p, there was minimal inhibition of CT. Thus, in yeast under conditions where PC is abundant, there is a feedback inhibition of CT and the CDP-choline pathway.

CTα has classically been considered to be a cytoplasmic enzyme since its activity is found in the cytosol and on microsomal membranes in cellular homogenates. However, immunofluorescence studies have demonstrated that CTα in CHO cells and many other cell lines is predominantly nuclear. In other studies, it was clear that in liver and primary hepatocytes, CT was predominantly cytoplasmic and was also present in the nucleus. Some of the CT in the cytoplasm is probably CTß, which does not have a nuclear localization signal. There is also evidence for the shuttling of CTα from the nucleus into the cytoplasm during active periods of PC biosynthesis.

CTP has also been implicated as being regulatory in animal systems and yeast. Overexpression of CTP synthetase in yeast

stimulated the biosynthesis of PC via the CDP-choline pathway.

2.8.1 Transcriptional and Posttranscriptional Regulation of CTα

Most studies on CT activity and PC biosynthesis have not indicated regulation at the level of gene expression. The ability of a cell to activate the soluble form of CT would normally satisfy the cell's requirement for PC. Nevertheless, some control over the expression of the genes encoding CT must occur. The proximal promoter of the *CTα* gene has numerous potential regulatory elements. Subsequent studies showed that Sp1, the first mammalian transcription factor purified and cloned, had an important role in regulating the expression of the *CTα* gene. The related nuclear factor, Sp3, could also activate CTα transcription. DNase protection assays indicated several elements in the proximal promoter-bound unidentified nuclear factors. The yeast one hybrid system was utilized to clone the cDNA for one of these factors, and the transcription enhancer factor 4 (TEF4) was identified as a regulator of CTα transcription. More recently, Ets has also been identified as an activating transcription factor. These initial studies were based on experiments involving transfections with various cDNA constructs. The first experiments to search for transcriptional regulation in a cell physiology–relevant system were on CTα expression in a murine fibroblast cell line as a function of the cell cycle. During the G0 to G1 phase of the cell cycle, there is an increase in PC biosynthesis, but there was no enhanced transcription of the *CTα* gene. Instead, increased transcription occurred during the S-phase of the cell cycle, possibly to increase the amount of CTα in preparation for mitosis. More recent studies have shown that the increased transcription is due to enhanced binding of Sp1 to the proximal promoter.

Sterol response element binding proteins (SREBPs) play a critical role in regulating the expression of genes involved in fatty acid and cholesterol metabolism. Thus, researchers in several laboratories explored whether SREBPs might alter the expression of the *CTα* gene. It appears that SREBP can activate CT transcription by binding to an element on the promoter, but the major activation appears to be indirect via the synthesis of fatty acids that will cause CT translocation to the membrane.

Obviously, there is much to be done to elucidate the factors and DNA elements involved in transcriptional regulation of the *CTα* gene. The transcription of the *CTß* gene appears to be activated in neuronal cells when exposed to nerve growth factor. However, the identity of the factor(s) involved remains to be determined.

The level of CTα mRNA can also be regulated by alterations in mRNA stability. When a macrophage cell line was depleted of the colony-stimulating factor and then repleted, there was a fourfold induction of mRNA for CTα. The stability of CTα mRNA increased after the addition of the colony-stimulating factor. An increase in CTα mRNA in fetal lung type II cells has also been ascribed to enhanced mRNA stability.

Finally, enhanced turnover of CTα via the ubiquitin–proteosome pathway appears to be the mechanism by which tumor necrosis factor decreases the level of CTα in alveolar type II cells.

2.8.2 Transgenic and Gene-disrupted Murine Models of CTα

To determine if enhanced PC biosynthesis would protect macrophages from

excess cholesterol-induced toxicity, genetically modified mice have been generated. A truncated version of CTα lacking the phosphorylation domain was expressed specifically in macrophages of mice under control of the scavenger receptor promoter. These cells were protected from cholesterol-induced toxicity. In another approach, CTα expression was eliminated in macrophages using the Cre-lox method for selective disruption of a gene in specific cells. The lack of the *CTα* gene and hence decreased PC biosynthesis caused enhanced sensitivity to cholesterol loading. In the absence of cholesterol loading, the macrophages without CTα appeared normal, possibly due to increased expression of CTß2. Further studies on tissue-specific knockouts of CTα should provide further information on the function of this enzyme.

2.9 Regulation of Gene Expression in Yeast

The pathways for the biosynthesis of phospholipids in yeast were largely elucidated by Lester and coworkers in the late 1960s (Fig. 9). These pathways are similar to those found in other eukaryotes except that PS in yeast is made via a pathway similar to that found in *E. coli*, where CDP-DG reacts with serine to yield PS and CMP.

Considerable interest in yeast as a model system has developed over the past two decades. Reasons for choosing *S. cerevisiae* include a large knowledge base in classical genetics, knowledge of the sequence of the genome, the ease of making mutant strains, and the ability to grow large amounts of yeast. Whereas understanding the regulation of expression of phospholipid biosynthetic enzymes in animal cells is still in its infancy, considerable progress has been made in the yeast system. When yeast cells are grown in the presence of choline and inositol, the expression of the enzymes involved in the conversion of PA and glucose-6-P to PI, PC, and PE is depressed (Fig. 9).

Both positive and negative regulatory factors are involved in the regulation of expression of phospholipid biosynthetic enzymes in yeast. The *INO2* and *INO4* genes encode transcription factors that are required for the expression of inositol-1-P synthase (*INO1*). *In vitro* transcribed and translated proteins derived from *INO2* and *INO4* form a heterodimer that binds a specific DNA fragment of the *INO1* gene referred to as UAS_{INO}. Ino4p (the protein encoded by *INO4*) and Ino2p exhibit basic helix–loop–helix domains. The Ino2p-Ino4p heterodimer binds to UAS_{INO} of the *INO1* promoter that contains two copies of a binding site (CANNTG) for basic helix-loop-helix–containing proteins.

The *OPI1* gene encodes a protein that is a negative regulatory factor for phospholipid biosynthesis. Opi1p contains a leucine zipper, a motif implicated in protein–DNA interactions, and transcriptional control. *Opi1* mutants exhibit a twofold increase in the constitutive expression of inositol-1-P synthase and other enzymes involved in PI, PC, and PE biosynthesis. The mechanism by which Opi1p mediates its negative regulatory role is unknown. Opi1p does not interact directly with UAS_{INO} or with Ino2p or Ino4p. Phosphorylation of Opi1 by protein kinase C may be involved.

Recent experiments have identified other proteins that interact with Ino4p, indicating that there is still much to learn about transcriptional regulation of phospholipid biosynthetic genes in yeast. How the regulatory genes (*INO2, INO4, OPI1*)

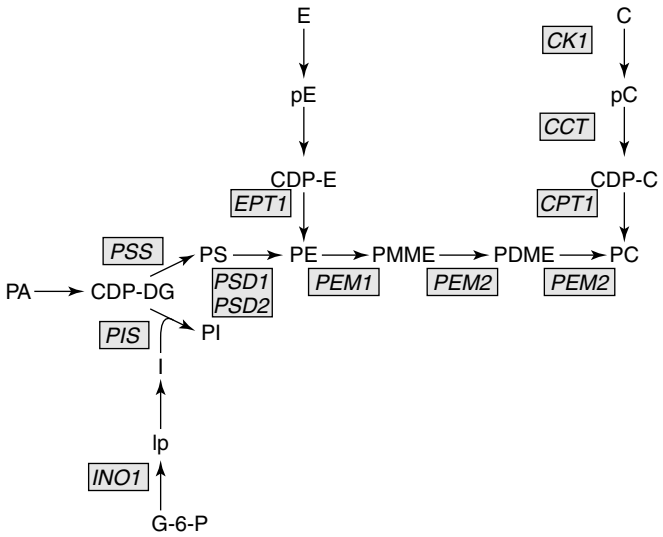

Fig. 9 Pathways for phospholipid biosynthesis in yeast and designation of the genes (italics in boxes) encoding the enzymes that catalyze the reactions. The abbreviations are E, ethanolamine; pE, phosphoethanolamine; CDP-E, CDP-ethanolamine; C, choline; pC, phosphocholine; CDP-C, CDP-choline; PE, phosphatidylethanolamine; PMME, phosphatidylmonomethylethanolamine; PDME, phosphatidyldimethylethanolamine; PC, phosphatidylcholine; PS, phosphatidylserine; PA, phosphatidic acid; CDP-DG, CDP-diacylglycerol; PI, phosphatidylinositol; I, inositol; Ip, inositol phosphate; G-6-P, glucose-6-phosphate. The genes encode the following enzymes: *INO1*, I-1-P synthase; *PIS*, PI synthase; *PSS* (also known as *CHO1*), PS synthase; *EPT1*, CDP-E:1,2-diacylglycerol ethanolaminephosphotransferase; *PEM1* (*CHO2*), PE methyltransferase; *PEM2* (*OPI3*), phospholipid methyltransferase; *CK1*, choline kinase; *CCT*, CTP:phosphocholine cytidylyltransferase (abbreviated as CT elsewhere in this chapter); *CPT1*, CDP-C: 1,2-diacylglycerol cholinephosphotransferase; *PSD1* and *PSD2*, PS decarboxylase.

are themselves regulated is just beginning to be studied.

3 Phospholipid Transport

The bulk of cellular phospholipids are made on the ER. How these lipids are directed to other cellular membranes is an important question of current interest. For example, PC is made on the ER and not on the mitochondria. However, approximately 30% of the phospholipids in mitochondria are PC. How does PC move to the mitochondria and what regulates this process?

Three modes are currently being considered for transport of phospholipids intracellularly: phospholipid transfer proteins, vesicular transport, and membrane continuity between adjacent organelles.

3.1 Phospholipid Transfer Proteins

These are low molecular weight proteins (14–18 kDa) that were first discovered in 1968 by Wirtz and Zilversmit. These proteins bind a single molecule of phospholipid and catalyze an exchange of phospholipids between donor and acceptor membranes. There are three categories of these exchange proteins: (1) those that are specific for PC; (2) those that prefer PI but also have transfer activity with PC; and (3) nonspecific transfer proteins that transfer most phospholipids and cholesterol. Several of these proteins have been purified, sequenced, and cloned. Considerable information is, therefore, available about the properties and *in vitro* activity of the transfer proteins. What has been lacking is evidence that the proteins actually function in cells as phospholipid transfer proteins.

The first success on understanding the possible function of the phospholipid-transfer proteins occurred several years ago when Dowhan and colleagues successfully inactivated the PI/PC transfer protein gene in yeast and demonstrated that the gene product was an essential protein. The authors correctly noted that this did not prove that the protein functioned in the transfer of PI or PC in the organism. Shortly thereafter, Bankaitis, Dowhan, and colleagues demonstrated that the *PI/PC* gene in yeast was identical to the previously identified *SEC14* gene. *Sec14* mutants of yeast are defective in secretion, fail to grow, and accumulate large amounts of Golgi membranes. Further research demonstrated that suppresor mutants of *sec14* (normal growth and function are recovered), which still had no PI/PC transfer protein, were defective in the biosynthesis of PC via the CDP-choline pathway. Thus, the PI/PC protein was somehow involved in regulation of the PI/PC ratio of Golgi membranes, and a decrease in PC biosynthesis achieved the same result. When PC is bound to the PI/PC transfer protein, it inhibits CT of the CDP-choline pathway. When PI is bound, there is no effect on CT activity. Thus, in the absence of the PI/PC transfer protein in *sec14* mutants, the biosynthesis of PC is unregulated so that PC accumulates in the Golgi and somehow causes Golgi dysfunction. Hence, at least in the case of *sec 14*, the transfer activity of the protein does not appear to be involved directly in lipid transfer, but rather in the binding of PC or PI to this protein, and the ligand that is bound determines the effect on CT activity. Further studies are required to elucidate the function of other phospholipid transfer proteins.

3.2 Vesicular and Contiguous Transfer of Phospholipids

A very attractive mechanism for movement of phospholipids from ER and Golgi (which also has the capacity for phospholipid biosynthesis) to other membranes is by vesicular transport. It is well known that this is how proteins are moved within cells to the plasma membrane or for secretion. The vesicles have phospholipid bilayers and fuse with target membranes. Therefore, it seems certain that some component of phospholipids in membranes such as the plasma membrane is delivered via this vesicular transport. Whether vesicular transport is the only source for plasma membrane phospholipids remains uncertain.

How mitochondria receive phospholipids and how PE, specifically made in mitochondria by the decarboxylation of

PS, is delivered to other organelles are questions of current interest. Voelker has used the organelle-specific decarboxylation of PS as a tool to study the mechanism of transport of PS, made on the ER, to the mitochondria. His studies have shown that the process does not require cytosol (source of phospholipid transfer protein) or PS biosynthesis, requires ATP, and may involve a membrane continuity between the ER and mitochondria. In agreement with the idea that there may be some type of noncovalent bridge between ER and mitochondria, J. Vance has isolated a MAM that is enriched in PS synthase compared to ER, has a protein composition similar to, but different from ER, and has low activity of a classical ER marker, nicotinamide adenine diphosphate (NADPH) cytochrome c reductase. If membrane continuity between the ER and mitochondria could be demonstrated, this might also be an explanation for much of phospholipid transport between the ER and other intracellular membranes such as the nuclear membrane and lysosomes. Then, the question of how the phospholipid composition of organelles is regulated can be addressed.

3.3 Genetic Analysis of Phospholipid Transport in Yeast

Selection of yeast mutants that require ethanolamine for growth has provided novel information about the transport of PS from the ER to mitochondria or Golgi. In the transport of PS to the Golgi, two mutant genes have been identified. One encodes a PI-4-kinase and the second gene encodes a protein that is closely related to the PI transfer protein encoded by the *SEC14* gene (Sect. 3.1). The process of PS transfer seems complex and it will be a challenge to unravel how these and other proteins are involved in the transfer of PS to the Golgi and mitochondria.

4 Functional Aspects of Phospholipids

4.1 Sources of Second Messengers

Phospholipids as a source of cellular second messengers is a relatively new concept. It has been known for several decades that phospholipids store arachidonic acid that is released for the biosynthesis of eicosanoids. These, however, are not truly second messengers, but are hormones that act on nearby cells. Approximately 40 years ago, there was a clue that derivatives of PI might be playing a signaling role in cells when Hokin and Hokin observed the rapid turnover of PI in pancreatic extracts from pigeon incubated with acetylcholine. However, significant progress occurred only in the early 1980s when it was recognized that within 20 to 30 s after the binding of an agonist to a receptor, there was a rapid catabolism of PI-4,5-P_2 to DG and inositol-1,4,5-P_3. It is now known that this process involves a coupling between the receptor on the cell surface and a phospholipase C by trimeric guanidine triphosphate (GTP) binding proteins.

Ten isoenzymes of PI-specific phospholipase C have been identified. All isoenzymes require calcium and degrade PI, PI-4-P, and PI-4,5-P_2. Which lipid is preferentially degraded depends on the conditions of the assay, but PC and PE are not substrates. Although these phospholipases have been purified from cytosol, the substrate is in the plasma membrane, and this is the probable site for hydrolysis.

The inositol-1,4,5-P_3 mediates the release of calcium from the ER. A receptor on the ER has been identified

that has a molecular weight of 313 kDa and binds inositol-P_3, besides having calcium-channel activity. Calcium released by this mechanism after the binding of vasopressin to hepatocyte receptors is known to be involved in the activation of phosphorylase.

The other product of PI-4,5-P_2 hydrolysis is DG and this appears to function as a second messenger by the activation of protein kinase C. This kinase was discovered in 1977 by Nishizuka and coworkers and has been shown to phosphorylate many different cellular proteins. Such phosphorylated proteins are involved in the regulation of cellular processes such as secretion, exocytosis, gene expression, and down-regulation of receptors. For example, the epidermal growth factor receptor is a substrate for protein kinase C. When this receptor is phosphorylated, it exhibits a decreased binding of the growth factor and its tyrosine kinase activity is attenuated.

Ten isoenzymes of protein kinase C have been identified and there may be more. All have a regulatory domain and a kinase domain. Protein kinase C exists in the cytosol as an inactive reservoir. On the generation of DG in the plasma membrane, the kinase binds to the membrane in which it is activated. Some isoenzymes of protein kinase C require calcium and PS for activity, whereas others do not.

More recently, there has been evidence that ceramide derived from SM hydrolysis might be a cellular second messenger and may activate a protein phosphate phosphatase. Similarly, DG released from PC hydrolysis has been implicated as a second messenger in cells. It is likely that we are only now seeing the ''tip of the iceberg'' with respect to the production of cellular second messengers derived from phospholipids.

In 1979, a potent, biologically active phospholipid was discovered that could aggregate platelets at a concentration of 10^{-11} M. The compound is now usually referred to as *platelet-activating factor* (PAF) and the structure has been identified as 1-alkyl-2-acetyl-*sn*-glycerol-3-phosphocholine. Thus, PAF is an unusual derivative of PC in which there is an ether-linked alkyl chain on carbon 1 and an acetyl group, rather than a long-chain fatty acid, on carbon 2 of the glycerol backbone. Various blood cells, healthy tissues, and tumor cells can synthesize and degrade PAF. PAF exerts many different kinds of biological responses. For example in neutrophils, PAF causes aggregation and degranulation responses, induces chemotaxis, increases cell adherence, enhances the respiratory burst, and stimulates the release of arachidonic acid for eicosanoid production. PAF has been implicated as a contributing factor in diseases such as asthma, hypertension, allergies, inflammation, and others. Specfic receptors for PAF are present on the plasma membrane of cells and thus most of PAF's effects seem to be mediated through receptors.

4.2 Anchoring of Proteins to Membranes

Most proteins on the exterior surface of cells are linked to the plasma membrane through a transmembrane domain. Over a decade ago, it was discovered that a variety of cell surface proteins are linked covalently to a glycosyl PI (GPI) in the plasma membrane. The GPI anchors bind a wide variety of proteins to the cell surface, such as hydrolytic enzymes, cell surface antigens, protozoan antigens (the most intensely studied is the variant surface glycoproteins of *Trypansoma brucei*), and proteins involved in cell–cell interactions.

The advantage to the cell of having cell surface proteins attached via the GPI anchor is not known. However, proteins linked in this manner can be released from the cell surface by hydrolysis of the PI moiety. A specific phospholipase D, which hydrolyzes the bond between the phosphate and inositol moiety, has been purified from human serum and cloned. Thus, one possible role for the GPI anchor would be to allow selective release of proteins from the cell surface. The release of glycoprotein antigens from the cell surface of *Trypanosomes* may be primarily involved in the parasite's ability to evade the immune system of infected hosts.

The core structure of GPI consists of PI linked to glucosamine, which is attached to a string of 3 mannose residues. To the terminal mannose, an ethanolamine phosphate residue is attached. The amine of the ethanolamine is linked to the carboxy terminus of the protein in an amide linkage. This core structure is found in a variety of cell types from brain to *T. brucei*. There are variations on the structure of the GPI moiety that include the addition of additional ethanolamine residues, fatty acids, and saccharides. In animal cells, the fatty acid at the 1 position of glycerol is often replaced by an ether-linked chain.

The biosynthetic pathway for the GPI anchor has now been established. Initially, there is a transfer of *N*-acetyl-glucosamine to PI followed by deacetylation. The mannose residues are then donated from dolichol-P-mannose. The ethanolamine P residue appears to be donated from PE. The proteins appear to be linked to GPI in the ER shortly after protein synthesis is completed. There is evidence that a transmembrane segment of the protein is hydrolyzed before or concomitant with addition of the GPI anchor.

5 Perspectives

The field of phospholipid research has entered a new and exciting period with the advent of molecular techniques. With the availability of various genomic sequences and the advent of proteomics, we can expect that most genes and proteins involved in phospholipid biosynthesis will be discovered in the next decade. Transcriptional regulation of phospholipid biosynthetic enzymes should emerge into a major area of research. The utilization of gene targeting will provide tremendous new insight into the function of these genes and proteins. The application of mass spectrometry to lipid analysis has emerged as lipidomics, where we can expect that most of the major lipids in a particular cell or tissue will be identified and quantitated. Variations in lipid compositions under various physiological perturbations (e.g. fasting, obesity) should provide new insight into the function of these lipids.

Transcription
Transcription is the process by which genetic information stored in DNA is copied into RNA transcript. It is achieved by recruiting DNA dependant RNA polymerase, which binds in the promoter region of the gene along with several other factors and slides down in a 3′ to 5′ direction on the complementary strand of DNA adding ribonucleotides to give an exact copy of the sense strand.

Transcript Processing
Majority of eukaryotic RNAs are synthesized as pre-RNA and processed posttranscriptionally to give a mature RNA molecule. Processing could include 5′ capping, 3′-end nucleolytic cleavage followed by polyadenylation, intron removal, alternative splicing, and RNA editing.

Translation
Translation is the process by which a mature transcript is translated into a polypeptide chain. This requires recruitment of ribosomal complex, aminoacyl tRNA, various translational and elongational factors on the mRNA and finally termination of the chain.

Cis-Elements and Trans-Acting Regulatory Factors
The cis-elements are DNA motifs present within and outside a gene including promoter and terminator regions and that allow other factors (known as *trans-factors*), mostly proteins, to bind with these in order to initiate/regulate transcription.

Photoreceptors
These are protein molecules with a chromophore, which sense light of different wavelengths and intensities and signal to provide various responses that lead to transcription of several genes.

Nuclear Organelle Genome Interaction
Chloroplast and mitochondria, though they have their own genome, depend largely on the gene products from nucleus, which are transported to these organelles and assemble together with organelle genome products to give a functional unit. The messages are mostly carried from nucleus to organelle; however, recently a vice versa interaction has also been reported.

Phytohormones
These are low molecular weight substances produced by plants, which exert their effects in very minute quantities mostly after binding to their receptors. The binding to the receptors evokes a cascade of events including expression of several genes (factors), which ultimately regulate expression of target genes.

Proteasome
This is a complex that degrades proteins marked by polyubiquitination, and brought to it by SCF complex. Various signaling pathways are activated by the proteasome proteolysis in order to transduce responses on the target genes.

Abiotic and Biotic Stress Responses
Plants sense various abiotic (heat, cold, drought, salinity, etc.) and biotic (pathogens, insects, herbivores) stresses and respond to these through hormones, metabolites, and

other physiological means that initiate protective measures by activating stress related genes.

MADS-Box Genes

These are transcription factors that possess a highly conserved 180 nucleotide domain known as *MADS box*. They are mainly involved in flower and fruit development and in plants contain an additional K-box for dimerization.

Epigenetic Regulation of Transcription

Activation and repression of genes by means that do not involve changes in the gene sequence. It includes transcriptional gene silencing (TGS) and posttranscriptional gene silencing (PTGS), is brought about by histone modification and DNA methylation as well as RNA degradation/inhibition of translation by siRNAs and miRNAs.

Eukaryotic genomes are much more complex than prokaryotes and plant genomes present more complexities than other eukaryotes. The continuous process of development, absence of germ-line, flexible and reversible cellular differentiation, polyploidy, and so on, are characteristic features that distinguish plant genomes from other eukaryotes. The complexities observed in plant genomes can possibly be attributed to three major factors. Firstly, plants are nonmotile and hence exposed to various environmental conditions constantly. In the absence of any neuronal network or immunological system, plants have evolved various local and systemic mechanisms to adapt to the environment to cope with biotic and abiotic stresses. This is achieved mainly through various signaling systems of phytohormones and other metabolites and the scores of genes participating in it. Secondly, plants from various species and genera synthesize about 45 000 different natural products or secondary metabolites. The functions of many of these are unknown; however, a number of these are used in defense, as attractants and volatile signals. This involves complex metabolic pathways involving several genes that require specific regulatory mechanism for expression. Thirdly, and the most puzzling attribute that still remains to be answered satisfactorily, is the variability observed in its genome size. The genome size as such is quite variable throughout the biological world; however, plants show the greatest variation of any kingdom in the biological world. For example, angiospermic plants that do not differ much in their basic activities contain a genome varying from 7×10^4 kb/haploid (*Arabidopsis*) to 1×10^8 kb/haploid (Lilly). Majority of the DNA in plant genome is not transcribed and may account for up to 90% of the genome on the basis of the number of active genes. Further, DNA motifs ranging in length from single base to thousands of bases, repeated many hundreds or thousands of time, are characteristics

of all eukaryotic genomes; however, plant genome may represent 50 to 90% or more of such DNA. The biological significance of this repetitive DNA is still not resolved properly. Of sequence motifs that are highly repeated, some are conserved from one species to another. Satellite DNA, minisatellite, variable-number tandem repeats (VNTR) are some of the major features of plant genome, which make them different from other eukaryotic genomes. The taxonomical usage of these sequences have added great knowledge in establishing phylogeny as well as biodiversity; however, whether they play any major role in plant gene expression and regulation is still not clear.

It was in the early 1960s that the basic principles of gene regulation and its expression in prokaryotes were established. While in prokaryotes the gene regulatory elements were defined as promoters, operators, and positive control elements, unfortunately the mechanism of eukaryotic gene regulation had to wait till recombinant DNA technology was in practice in the early 1970s. High throughput sequencing of genome (genes) and development of various softwares for the analysis of these sequences made it possible to look into functional and regulatory aspects of plant genome. On the basis of the information obtained through *Arabidopsis* and rice genome sequencing and various ESTs (Expressed-sequence tags), plants may express 25 000 to 50 000 genes depending upon species and genera. Of these, about 30 to 35% may be expressed in all parts of the plant (constitutive), whereas others could be organ specific or event specific. The gene product may localize to a certain cell type, appear only at a specific developmental stage, or accumulate following distinct environmental stimuli. More than one inducer may turn on some genes or a single stimulus may have different effects on different genes. The existence of cross talk between different hormones, light, and environment during plant development further complicated the task of defining gene regulation of expression in plants. Fortunately, gene transfer technology and development of mutants and functional genomics have added tremendously to the knowledge of gene expression, regulation, and its function. Reverse genetics is being applied to investigate the function of candidate genes through approaches such as RNA interference (RNAi), TILLING (target induced local lesions in genome) and use of systematically generated T-DNA populations. Comparative genomic approaches, as well as functional assays using mini chromosomes, hold great promise for understanding both cis-DNA elements and the trans-protein components.

In this article, we have tried to include some of the common and recent features of plant gene expression and its regulation. Though it is difficult to describe every gene regulation, the article will provide an overview of various classes of genes that are expressed in plants in general and the mechanism of their regulation. We will describe here topics like the basic mechanism of plant gene transcription and translation; hormonal and light regulation of genes; regulation of expression during biotic and abiotic stress; gene regulation during development; mitochondrial and chloroplast gene expression and regulation; and recent advances in plant gene expression and regulation. The emphasis has been given on the various DNA elements identified within and outside gene and transcription factors, which hold key to all gene expression and regulation.

1
Basic Mechanism of Plant Gene Expression

The flow of genetic information contained in a portion of genetic material, DNA, involves the generation of RNA molecule followed by synthesis of polypeptide. Understanding how the information in DNA is converted into functional proteins became possible through the discovery of messenger RNA and transfer RNA and the decoding of the genetic code. The process by which information in DNA is finally expressed as polypeptides is known as *Central dogma*. This includes three major steps. The first is replication, the copying of parental DNA to form daughter DNA molecules having identical nucleotide sequences. The second is transcription, the process by which parts of DNA are copied precisely to form RNA. The third is translation, in which the genetic message coded in mRNA is translated on the ribosome, through tRNA molecules, into a polypeptide with a specific sequence of amino acids. We will discuss here the process of transcription and translation pertaining to transcribed and/or translated region of the plant DNA. A schematic representation depicting the general mechanism of eukaryotic gene transcription and translation has been presented in Fig. 1

The first step in gene expression is transcription, the synthesis of RNA copy of DNA template. Studies have suggested that in addition to continuous presence of mRNA from constitutive genes, each organ in the plant contains a large number of organ specific mRNAs. Various protein complexes, that bind to DNA and are again subjected to various types of regulation, carry out the control of transcription. Much of our understanding of the basic elements of the transcription is derived from early work on the bacterial system; however, transcription in plants and other eukaryotes is far more complex than in prokaryotes. In prokaryotes, transcription is coupled to translation, that is, as the transcript elongates, it binds to ribosomes and begins synthesizing proteins. In eukaryotes, however, the nuclear envelope separates the genome from the translational machinery. This may allow selective movement of mRNA from the nucleus to reach the ribosomal machinery in cytoplasm for translation purposes. The expression of genes present in organelle genome of the mitochondria and chloroplast, differ from the expression of nuclear genome in that they follow a prokaryotic mode of transcription and translation and yet depend on nucleus for expression of their genes.

RNA polymerases and other DNA binding proteins are responsible for determining which genes are to be expressed at a particular time. For each gene, the transcription process can be conveniently divided into two stages. The first stage is the initiation of transcription and involves assembly of the complex of proteins, including the RNA polymerase enzyme and its various accessory polypeptides upstream of the gene. This step determines whether the gene is actually expressed. In the second stage, the RNA polymerase moves along the gene to synthesize the primary transcript, which is a direct copy of the gene. This second stage is often accompanied by RNA processing events, which include removal of introns, processing of 5′ and 3′ ends, and so on. We will examine each step one by one in more detail in the following section predominantly for nuclear genes. The organelle genome expression and regulation will be described separately at the end of this section.

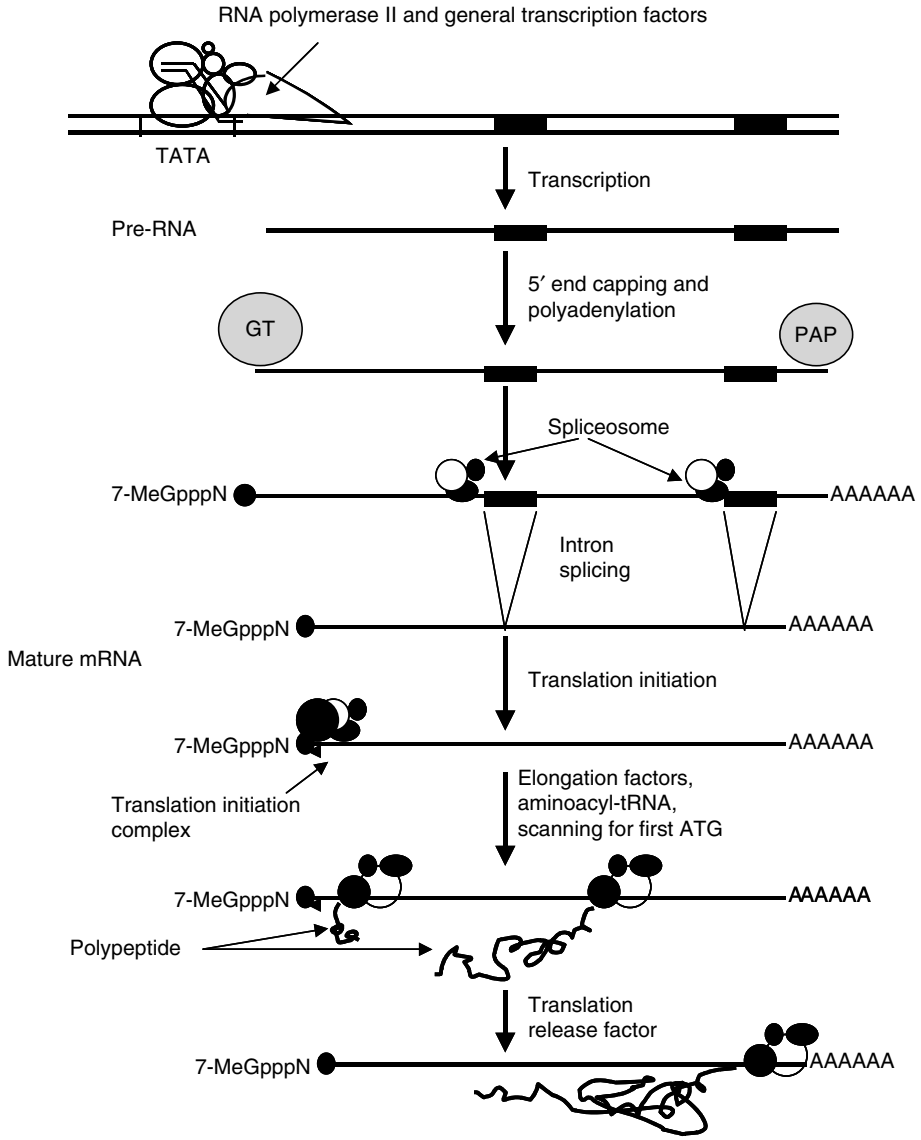

Fig. 1 Basic transcription and translation scheme during plant gene expression. GT, guanylyl transferase; PAP, poly(A) polymerase.

1.1 RNA Polymerases

The enzyme responsible for copying DNA into RNA is called *DNA dependent RNA polymerase*. Transcription of eukaryotic genes requires three different RNA polymerases, namely, RNA polymerase I, RNA polymerase II, and RNA polymerase III. These three RNA polymerases have different responsibilities and locations in the nucleus. RNA polymerase I, which

resides in the nucleolus is responsible for transcribing the genes coding for rRNA; RNA polymerase II is located in the nucleoplasm and required for synthesizing heterogeneous nuclear RNA (hnRNA), the precursor for mRNA. RNA polymerase III is a minor enzyme, located in the nucleoplasm and synthesizes tRNAs and other small RNAs. All plant and other eukaryotic RNA polymerases are large multisubunit (8–12 subunits) proteins with a molecular weight more than 500 kDa. Structurally, these polymerases are quite similar to each other. The largest subunit in RNA polymerase II has a carboxy-terminal domain (CTD), which consists of multiple repeats of the consensus sequence Tyr-Ser-Pro-Thr-Ser-Pro-Ser. The sequence is unique to RNA polymerase II. The number of repeats is important, because deletion or removal of more than half a repeat is lethal. The phosphorylation/dephosphorylation of this domain at serine or threonine residue determines the initiation of transcription.

The RNA polymerases that transcribe organellar genes are prokaryotic in nature unlike their counterparts in the nucleus, reflecting the bacterial origins of mitochondria and chloroplast. The organelle genomes are much smaller, hence, the RNA polymerase needs to transcribe relatively few genes, and the control of transcription is likely to be simpler. The mitochondrial RNA polymerase, encoded by the nucleus, consists of a single subunit with a molecular mass of 140 kDa. This enzyme is very closely related to bacteriophage RNA polymerase. The mitochondrial polymerase works in conjunction with other accessory polypeptides. Chloroplasts have RNA polymerases encoded by chloroplast genome as well as nuclear genome. Both types of RNA polymerases are involved in transcription of different sets of genes present in chloroplast.

1.2 Promoters and Other Regulatory Elements

In plants and other eukaryotes, the term ''promoter'' is used to describe all the nucleotide sequences that are important in initiation and regulation of transcription of genes. For some genes, these sequences can be numerous and diverse in their functions, including not only the ''core promoter'' or ''basal promoter,'' which is the site at which initiation complex is assembled but also one or more elements upstream of the core promoter. We can divide the structure of a plant promoter into two parts, the core (basal) or minimal promoter, consisting of the minimum upstream sequence required for gene expression, and the additional regulatory sequences that control the activity of the core promoter. Each of the three RNA polymerases binds to a different type of promoter. RNA polymerase I promoters consist of a core promoter spanning the transcription start site, between nucleotide −45 to +20, and an upstream control element. The minimum promoter for genes transcribed by RNA polymerase II typically extends about 100 bp upstream of the transcription initiation site and includes several sequence elements referred to as *proximal promoter sequences*. The TATA box, which plays a crucial role in the transcription has been found to be located about 25 to 30 bp upstream of the transcription start site. It has a sequence of TATAAA(A) and serves as a site for assembly of the transcription initiation complex. Approximately 85% of the plant genes sequenced so far contain TATA box. In addition to the TATA

box, the minimum promoter also contains "CAAT box" and "GC box." These two regulatory elements are the site for binding of transcription factors, proteins that enhance the rate of transcription by facilitating the assembly of the initiation complex. Because these sequences are adjacent to the transcription unit, they are considered regulatory and known as *cis-acting sequences*. The transcription factors that bind to the cis-acting sequences are called *trans-acting factors*, since the genes encoding these are located elsewhere in the genome. Various cis-acting elements and their respective trans-acting factors for the regulation of genes during plant growth and development has been shown in Fig. 2.

Numerous other cis-acting sequences are found to be located further upstream of the proximal promoter and exert either positive or negative control over plant gene expression. These sequences are termed *distal regulatory sequences* and these are usually located within 1 kbp of the transcription initiation site. The positively acting transcription factors binding to these sites are known as *activators* whereas the negative transcription factors binding to these sequences are known as *repressors*. In addition to having regulatory elements within distal regulatory sequences, plant as well as other eukaryotic genes are also regulated by other control elements located tens of thousands of base pairs away from the transcription start site. These elements are known as *enhancers* and may be located either upstream or downstream from the distal regulatory sequences. In plants, many developmentally important genes have been shown to be regulated by enhancers.

RNA polymerase III promoters are unusual in a way that they are located in the gene for which they promote the transcription. These promoters are variable and fall into three different categories. Usually, the core promoter spans approximately 50 to 100 bp. One category of RNA polymerase III is very similar to RNA polymerase II with a range of upstream promoter elements.

1.3 Assembly of the Transcription Initiation Complex

In *Escherichia coli*, a direct contact is established between the promoter and RNA polymerase, whereas in plants, as well as in other eukaryotes, transcription initiation is much more complex. For genes transcribed by RNA polymerase II, the initiation contact is made by the general transcription factor, TFIID (Transcription Factor of RNA polymerase II protein D), which is a complex made up of the TATA-binding proteins (TBP) and at least 12 TATA-binding protein-associated factors (TAFs). Most of these proteins are DNA-binding proteins and have sequence specificity. Both TBP and TAFs appear to have important function in recognition and are indispensable, at least for some genes. The TFIID recognizes the TATA component of the RNA polymerase II core promoter. After TFIID has attached itself to the core promoter, the preinitiation complex is formed by binding of additional general transcription factors in the order TFIIA, TFIIB, TFIIF/RNA polymerase II, TFIIE, and TFIIH. Some of these GTFs (general transcription factors) have DNA-binding properties and others interact purely by protein–protein interaction. The binding of TFIIF, recruits the RNA polymerase II to the complex. After that, TFIIH acts as a DNA helicase, which unwinds the DNA as well as acts as a kinase that adds phosphate

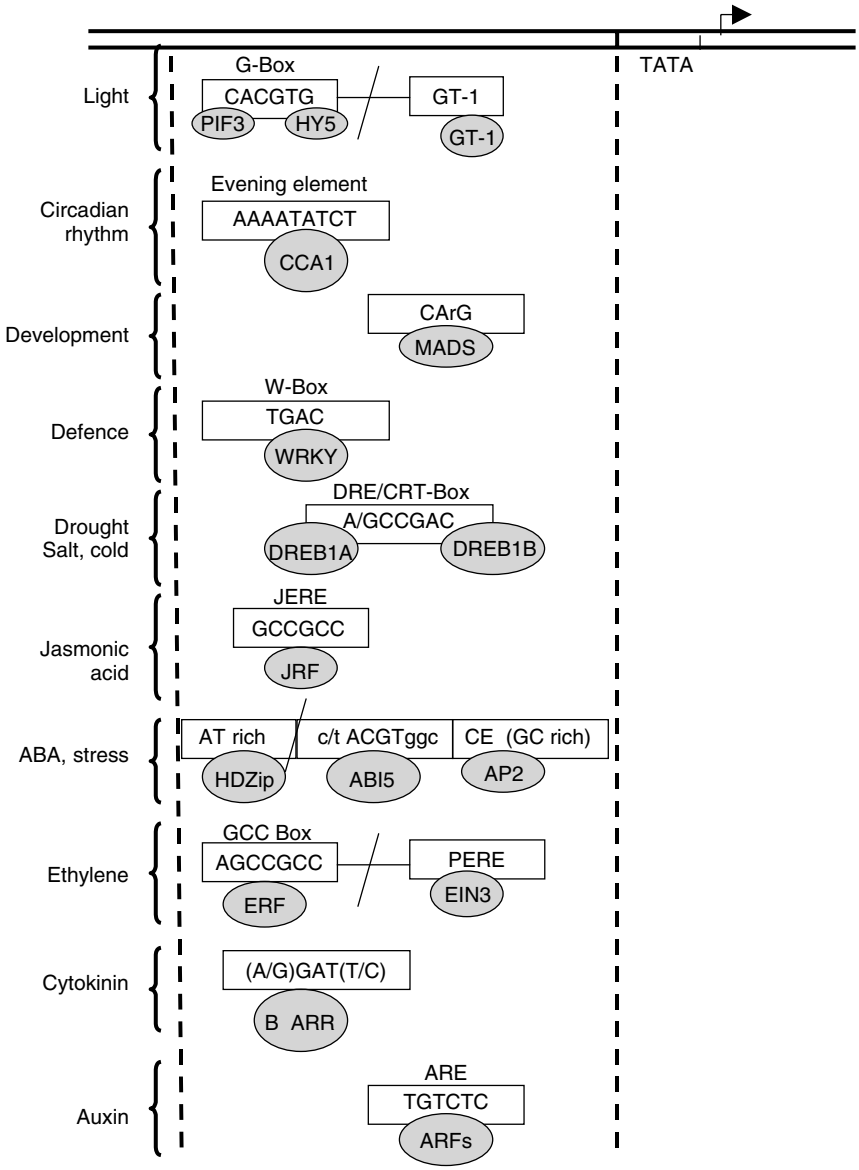

Fig. 2 Various cis-acting elements and associated trans-acting factors during plant gene expression in response to different stimuli.

group to the C-terminal domain of RNA polymerase II. RNA polymerase then separates from the initiation complex and proceeds along the antisense strand in the 3′ to 5′ direction. While some of the general transcription factors dissociate from the complex at this point, others remain bound for another RNA polymerase molecule and initiate another round of transcription.

1.4 Transcription Factors and Their Motifs

In most of the transcription factors, three structural features are invariably common. These are DNA binding domain, a transcription-activating domain, and a ligand binding domain. Some of the transcription factors are needed for the coordinated regulation of genes in plants and other eukaryotes. In plants, the effects induced by light and hormones as well as the adaptive responses caused by various types of stresses involve the coordinate regulation of the groups of the genes that share a common response element upstream of the promoter. The genes that act as major developmental switches, such as the homeotic genes, encode transcription factors that bind to common regulatory sequence present in dozens, or even in hundreds, of genes scattered throughout the genome. A detailed list of major transcription factors and genes regulated by these is given in Table 1.

1.5 RNA Processing

Many RNAs, especially in eukaryotes, are initially synthesized as precursor or pre-RNAs, which have to be processed before they can carry out their function. The most important processing events are splicing, 5′-end capping, polyadenylation, and RNA editing, which are carried out singularly or in conjunction depending upon the message type. Each of these processes is regulated and may provide a means by which expression of individual genes can be modulated. For example, the mRNA resulting from both editing and alternative splicing often displays tissue specificity thereby increasing the coding capacity of the genome without the requirement for additional copies of the relevant genes. We shall describe each processing event below in detail with respect to plants.

1.5.1 3′-End Formation

The poly (A) tail present in the 3′ end of the mature mRNA plays an important role in many aspects of RNA function and metabolism, particularly in mRNA translation and turnover. The mature 3′ end is formed by endonucleolytic cleavage followed by the addition of poly (A) tail to the 3′ end of the cleavage product. The 3′-end formation is a necessary prerequisite for the transcription termination. However, not much is known about mRNA 3′-end processing in plants. The discovery of the importance of the AAUAAA motif for polyadenylation in animal systems prompted the search for similar motifs in plant genes. The analysis suggested that the AAUAAA element is not a prerequisite for 3′-end formation in plants as more than 60% of the 3′ UTRs of the plant genes do not contain an exact match of this sequence at an appropriate position. AAUAAA is nevertheless found as a consensus of the 3′ UTR of many plant genes; however, the information regarding the elements required for the constitution of poly (A) signal is based on sequence comparisons and data from a small number of functional studies. Plant poly(A) signals appear to be much more diffuse, redundant, and complex as compared to their animal counterparts. To our knowledge, only three genes, one from dicot (pea rbcS-E9) and two from monocots (maize 27 kDa zein gene and wheat histone H3 gene) have been functionally analyzed for 3′-end formation. The modular architecture of a plant poly(A) signal can be described

Tab. 1 Major transcription factor families in plants (numbers are given for *Arabidopsis*).

Family	***Genes***	***Function***	***Examples***
Families specific to plants			
1. AP2/ERF	144		
a. AP2/RAV subfamily	20	Floral organ specification, seed development, cell identity	*ANT, APETALA2*
b. ERF subfamily	134	Ethylene response, abiotic stress, defense response	*ERF1, ERF3, ERF4, DREB1a, DREB1b*,
2. NAC domain	109	Auxin response, meristem development, organ separation	*NAC1, NAP, CUC1, CUC2*
3. WRKY	72	Defense response	*tWRKY3, tWRKY4*
4. DOF/CO-like/YABBY (Zn-C2C2 subfamily)	70	Flowering time, circadian rhythm, seed germination, carbon metabolism, abaxial cell fate	*CO, DAG1, CRC*
5. GARP	56	Cytokinin response, photosynthetic development, abaxial cell identity	*ARR1, ARR2, KAN1, PHR1*
6. GRAS	32	Gibberellin response, phytochrome response, root, shoot development	*GA1, RGA1, SCR, SHR*
7. Aux/IAA	27	Auxin response, root development	*IAA3, IAA7, AXR3*,
Families with a significantly higher representation in plants			
1. MYB family	190		
a. MYB (R1)R2R3	136	Stem cell function, trichome and root development, defense response, ABA response, phyA signaling	*GL1, AtMYB2, AtMYB4, LAF1*,
b. MYB related	54	Circadian clock, root development	*CCA1, LHY, CPC*
2. MADS Box	82	Meristem identity, flower and fruit development, abscission, flowering time	*AG, AP1, FLC, SEP1, SEP2, RIN, SHP1, GL15*,
Other major families			
1. basic HLH	139	Phytochrome responses, trichome, root development, abiotic stress response, secondary metabolism	*PIF3, HFR1, rd22BP1, GL3*
2. C2H2 (Zn)	112	Organ development, flowering time, abiotic stress, light response	*EMF2, SUP, VRN2*
3. Homeodomain	90	Development (leaf, stem, root, ovule), stem cell identity, sucrose signaling, shade avoidance	*PHV, REV, STM, WUS, KNOX, ATHB, KNAT1*,
4. bZIP	77	Photomorphogenic response, flower, leaf development, defense, ABA, GA response	*HY5, HYH, ABI5, PAN*

by three features – the near upstream element (NUE), the far upstream element (FUE) and the cleavage site itself. The NUEs characterized to date range from AAUAAA-like motifs to rather unrelated sequences. Although often present in a variant form, the FUE is present in all plant poly(A) signals characterized indicating a requirement for this element to enhance the overall processing efficiency. This is presumably achieved via interaction with protein factors belonging to the processing complex. The FUE of different plant poly(A) signals are interchangeable demonstrating their functional conservation. No conserved sequence element common to all FUE has been reported though they contain U- or UG-rich sequences. Examination of poly(A) sites reveals a consensus of YA at the cleavage site. It has been suggested that the cleavage site itself be defined as a cis-acting component of the poly(A) signal in plants. However, in most cases where the original cleavage site is removed or mutated cleavage still takes place at an appropriate position downstream of a functional NUE/FUE, although with less precision. Taken together, it suggests that although certain nucleotides are preferred as the substrate for a cleavage site, the cleavage site is determined by the position of the NUE.

The exact model for the 3′-end formation in plants is not clear. It seems that cleavage and polyadenylation specificity-like factor (CPSF-like), cleavage stimulation factor (CST-like) and cleavage factor (CF) in addition to poly(A) polymerase play important roles in 3′-end formation in plants. A protein, which has been shown to influence 3′-end processing via interaction with upstream sequences, is the U1 snRNP (U1A) in mammals. The cloning of U1A from potato and *Arabidopsis* revealed that the autoregulatory mechanism present in mammals is not conserved in plants.

Apart from NUE and FUE, the presence of Poly (A) polymerase (PAP) itself can safely be assumed in higher plants. PAP enzyme has been cloned from different sources. Owing to lack of any direct nucleotide sequence homology, it has not been possible to use either the mammalian or yeast PAP clones as molecular probes to isolate a plant homolog. The PAP activity in plants was first reported more than 25 years ago and has been described in a diverse range of plants such as cotton, maize, wheat, pea, and tobacco. A cDNA from pea seedling encodes a polypeptide, which was found active as poly(A) polymerase either in association with RNA binding factor or free polyA as RNA substrate.

1.5.2 5′-End Capping

Another modification before pre-RNA is processed is the 5′-end capping by the addition of 7-methylguanosine at the 5′-end of the transcript via a 5′-to-5′ linkage. The pre-RNA is capped almost immediately after initiation of mRNA synthesis. One of the functions of the 5′ cap is to protect the growing RNA transcript from degradation by RNases. A nuclear enzyme, guanylyl transferase, catalyzes the addition of terminal G at the 5′ end.

Poly(A) tail and 5′-end capping have several functions. They protect transcripts against RNases and therefore increase stability of the transcript. Both the processes are required for transit of the RNA from nuclear pore and increase the efficiency of the translation on the ribosome. The requirement of eukaryotic mRNAs to have both the 5′-cap and poly(A) tail ensures that only properly processed transcripts will reach the ribosome and be translated. By electroporating capped or uncapped

mRNAs and mRNAs with or without poly(A) tail into tobacco protoplast, it has been found that 5′ cap stabilizes reporter transcript two- to fourfold and the poly(A) tail stablizes reporter transcript two- to threefold. Although it is unclear how the 5′-cap and poly(A) tail protect the mRNAs from degradation, an appealing model would be that the physical interaction between the cap and poly(A) tail via their associated factors would sequester the ends of the transcript, protecting them from nucleases.

1.5.3 Splicing of Introns

The removal of introns or untranslatable sequences from pre-mRNA transcript and the concomitant ligation of exons is known as *pre-mRNA splicing*. It is a fundamental feature of gene expression in eukaryotes and a key step at which expression is regulated. Higher plant genes contain introns and the majority contains multiple introns. The gene encoding the 140-kDa subunit of RNA polymerase II in *Arabidopsis* contains 24 introns while the gene encoding acetyl-coenzyme A carboxylase contains 34 introns. Genes encoding highly conserved eukaryotic proteins such as histones, which lack introns in mammals, can contain introns in plants. However, introns are not a universal feature of plant genes, for example, maize zein genes lack introns.

Higher plants introns vary widely in length, but around two-third are shorter than 150 nt and most fall within the size range of 80 to 139 nt. A minimum functional length of 70 nt has been determined for efficient processing of synthetic introns in higher plants and consistent with this, naturally occurring introns shorter than 70 nt are rare. Very few introns in plants have been reported to be more than 2 to 3 kb, for example, maize *pericarp* gene, which has intron of 7 kb. Higher plant introns, belonging particularly to dicots, are characteristically AU rich. Introns of dicot origin average 70% AU and very few (2%) have an AU content less than 59%. Pre-mRNA splicing in monocots does not exhibit the same requirement for AU-rich sequence. Introns of monocot origin average 60% AU, but many (38%) have an AU content less than 59%, with some being as low as 30 to 35%.

The 5′ splice site dinucleotide/GU is conserved in virtually all naturally occurring plant introns. However, in rare instances, the 5′ splice site dinucleotide is /GC. A /GC 5′-splice site is conserved in seven myrosinase genes characterized from three different plant species. The wider 5′-splice site consensus in higher plants, AG/GUAAGU, matches that derived from mammals. The 3′-splice site dinucleotide, AG/, is invariant in naturally occurring higher plant introns. Mutation of the terminal AG/ by deletion, substitution, or point mutation of the terminal G results in abolition of its use. Point mutation in the 3′-dinucleotide AG to UG in maize *bronze*-2 intron abolished processing. The wider consensus derived from plant 3′-splice sites (UGYAG/GU) though it resembles, is more extensive than those for mammals (YAG/G).

Pre-mRNA splicing can, but need not necessarily, occur cotranscriptionally. It takes place within a large ribonucleoprotein complex termed as *spliceosome*. This spliceosome assembles on pre-RNA in a stepwise manner governed by multiple cis-acting elements. Interest in pre-RNA splicing in higher plants increased when it was realized that heterologous introns are not usually processed in transformed plant cells. This indicated that splicing in plants has some unique requirements that

distinguish it from mammals and yeast. The major subunits of the spliceosome are uridylate-rich small nuclear ribonucleoprotein particles (U snRNPs), U1, U2, U4/6 and U5. In addition to spliceosomal U snRNPs, a number of other non-U snRNP proteins are essential for constitutive and regulated splicing. The U snRNPs assemble on the pre-mRNA via an ordered pathway that requires the transient association of diverse non-U snRNP proteins. The defined pathway of assembly and disassembly is called *the spliceosome cycle*. Nascent pre-RNA transcripts first associate with multiple distinct heterogeneous ribonucleoprotein particles (hnRNPs) to form hnRNP complex. This complex is not a functional intermediate in spliceosome assembly, nor a complex specific to the splicing reaction but a substrate recognized by spliceosome machinery. After this, a stepwise complex is formed with spliceosome to process the introns. This stepwise assembly of the spliceosome mediates dynamic array of RNA–RNA interaction at the heart of the catalytically active complex.

Each of the key RNA sequences that form the dynamic skeleton of the spliceosome are conserved in higher plants: the 5′ sequence of U1 snRNA that interacts with 5′ splice site; the U2 sequence that interacts with the branch site and forms helix I with U6; the U5 loop I sequence that makes exons interact; and the U6 sequence that interacts with U2 in helix I and 5′ splice site, are all invariant among plant U snRNAs. Genes encoding each of the spliceosome snRNAs, U1, U2, U4, U5, and U6 have been cloned from several different plant species and analysis suggest that these are highly conserved with their mammalian counterparts in terms of size, sequence, and secondary structures. The fundamental mechanism of pre-RNA splicing in higher plants, in all likelihood, closely resembles that of yeast and mammals. The most direct evidence in support of this observation comes from the demonstration that the splicing in plants is through a branched lariate intermediate.

1.5.4 Alternative Splicing

Primary transcripts of many genes arising from a single transcription unit in animals can be differentially spliced to produce multiple mRNAs giving rise to proteins with different function. The process is needed to regulate gene expression during development and/or in a tissue-specific manner. The number of alternatively spliced genes reported so far in plants is much smaller than that of mammals, but with explosive growth of available EST and genomic sequences the number is increasing. There are five basic models for a gene to be internally and alternatively spliced. In the first model, the intron is retained with the exon. In the second and third models, the intron is alternatively spliced because of alternative donor or acceptor site, which causes part of the intron to be spliced from the pre-RNA. The fourth possibility arises due to exon skip and in that case the donor and acceptor sites of two different introns work together, which results in an mRNA lacking an exon between the two introns. In the fifth model, splicing takes place because of mutually exclusive exons. There are two additional models for alternative splicing and they depend on transcription start selection and transcription termination selection. More than one possibility can apply to the same gene, and the combinations result in a tremendous variation in gene products.

Recent data indicate that intron retention is the most common form of alternative splicing in plants and account for more than 30% of all alternative splicing. Recently, one database ''Plant Alternative Splicing Database'' (PASDB) has been created with the sequence information of all plant species under *Viridiplantae*. Examples of alternative splicing in plants include rubisco activase, which is a nuclear-encoded chloroplast protein required for the light activation of ribulose 1,5-bisphosphate carboxylase/oxygenase *in vivo*. In most of the plants that are known to have a spliced variant for this gene, two isoforms were found that differ only at the carboxy-terminus, resulting from alternative splicing of a common pre-RNA. In *Arabidopsis*, both isoforms can activate rubisco activity, although light modulation of rubisco activity requires the larger rubisco activase isoform. Alternative splicing has also been observed in MADS-box genes. Spliced variant of MADS-box genes have been reported in maize, barley, rose, and blue gum. Another example of alternative splicing in rice and maize is granule bound starch synthase, an enzyme that is responsible for the synthesis of amylase. Similarly, the starch branching enzyme, which defines the chain length and frequency of branch points for amylopectin, is also known to alternatively splice in maize, rice, wheat, and kidney bean. Recently, phosphoenolpyruvate carboxylase kinase gene has been shown to alternatively splice in different members of *Solanaceae*.

1.6 Translation

Translational efficiency of any system is defined as the rate of polypeptide synthesis per mRNA per unit time. Levels of protein synthesis are therefore determined not only by message abundance but more so by the ability of the transcript to be successfully translated. The translation of mRNA to polypeptide is divided into three different steps. In the first step, the mRNA is recruited to the ribosome (initiation). In the second step, polypeptide chain synthesis takes place (elongation) whereas in the third step, polypeptide chain is released from the translation machinery for further processing (termination). In plants, translation is frequently controlled at initiation and appears to be regulated by competition for limiting translational components, different requirement of specific factors, and cis-acting mRNA elements.

1.6.1 Initiation of Translation

Recruitment of mRNA for translation is a complex process that requires interactions between the mRNA, the two ribosomal subunits and at least nine translational factors, as well as the hydrolysis of ATP and GTP. Many initiation factors (eIF1 to eIF6) have been identified in plant and their role in protein synthesis has been established. In cap-dependent translation, the initiation factor 4 (eIF4) components are responsible for the selection of 5′-capped transcripts and the removal of the secondary structure to facilitate 5′-to-3′ migration of 40S preinitiation complex toward the initiator AUG. The preinitiation complex includes the mRNA, elF4 proteins, eIF2-tRNA^{met}-40S ribosomal subunit complex, eIF3, eIF1A, and eIF5. The preinitiation complex searches for the first AUG triplet. The recognition of the first AUG triplet is assisted by eIF1 and eIF1A. The binding of the 60S ribosomal subunit and hydrolysis of GTP complete the initiation. Sometimes specific trans-acting factors are needed for efficient translation initiation.

A protein that binds to the 5′-GpppN cap of the mRNA mediates the first phase of recruitment of mRNA for translation. In mammals, availability of the cap-binding protein eIF4E is regulated by its interactions with 4E-binding proteins. Plants possess at least three distinct cap-binding proteins. The plant eIf4E homolog interacts with the plant eIF4G homolog. There is also a second and distinct cap-binding protein, eIFiso4E that is apparently unique to plants. This protein interacts with eIFiso4G, an 86-kDa protein unique to plants that also interacts with eIF4A, eIF4B, and poly(A) binding protein. A third cap-binding protein, nCBP, was identified in *Arabidopsis*. It interacts with eIF4iso4G in the yeast two-hybrid systems and functionally replaces eIF4E or eIFiso4E in an *in vitro* translation system.

Factors that regulate the initiation of translation include phosphorylation/ dephosphorylation of factors and 5′- and 3′-UTR interaction. The eIF4A is present in phosphorylated as well as nonphosphorylated forms. The level of phosphorylated eIF4A increases approximately 50% in response to oxygen deprivation and heat shock. The phosphorylation status of eIF4A and eIF4B might influence protein–protein or protein–mRNA interaction, which is important for mRNA selection for translation. In plants, the phosphorylation of ribosomal protein S6 is observed in several instances. In *Arabidopsis*, heat shock results in S6 phosphorylation by heat inactivation of the S6 kinase. Presence of 5′-cap structure and a 3′-poly(A) tail promotes a synergistic enhancement of translation of mRNA in plants and yeast cell protoplast. These observations suggest that interaction between the 5′-and 3′-termini causes circularization of actively translated mRNAs. In plants, 5′ to 3′-interaction via PABP and cap-binding complex might be further promoted by elF4B because this factor stimulates binding of PABP to poly(A). The 5′ to 3′-interaction might promote the selection of mRNA for initiation, ribosome cycling, and/or to ensure that the 5′ end is correctly capped and transcripts are polyadenylated.

1.6.2 Elongation of Polypeptide Chain

Elongation of polypeptide chain is carried out by various factors, that is, elongation factors (eEF1A, eEF1B, and eEF2), different aminoacyl-tRNAs, GTP, and ribosomes. The elongation process in plant is very much similar to what is known for other eukaryotes and prokaryotes. The traditional role of eEF1 is to bring the correct aminoacyl tRNA to the A site on the ribosome in preparation for the next peptide bond to be formed during elongation. Plant eEF1, like in other eukaryotes, is composed of four nonidentical subunits (p52, p48, p36, and p34). The eEF1 has been isolated from a variety of plants. The p52, p48, p36, and p34 subunits are known as *eEF1A* (*EF-1α*), *eEF1Bγ*, *eEF1Bβ*, *and eEF1Bα* respectively. eEF1A is one of the most abundant proteins in the eukaryotic cell representing up to 5% of the soluble protein and has a very important function in making the elongation complex. The eEF1A is a member of GTPase super family and hydrolyzes GTP with the help of eEF1B. The amino acid sequence of this factor is highly conserved (>95%) between plant species. The expression of the gene responsible for encoding eEF1A is highest in plant tissues with rapid growth such as in meristem, root tips, young leaves, and developing ovules.

The eEF2 elongation factor catalyzes the GTP-dependent translocation of the peptidyl-tRNA from the A site to the P

site of the ribosome, resulting in the movement of the mRNA three nucleotide toward the 3′ end and release of deacylated tRNA from P site. eEF2 is also a member of the GTPase superfamily but in contrast to eEF1A, this does not need a recycling factor for the exchange of GDP to GTP. The most important feature of the eEF2 is that it is posttranslationally modified at His715 to yield a unique residue, diphthamide, found only in eEF2. This unique residue is the target for specific and covalent attachment of ADP-ribose to eEF2 for several bacterial toxins, which inactivates the eEF2 and leads to cell death. The phosphorylation of eEF2 by eEF2 kinase leads to inhibition of eEF2 activity.

1.6.3 Termination of the Polypeptide Synthesis

The process of release of the polypeptide chain from the ribosome begins when the ribosome encounters one of the three termination codons in the A site. A release factor binds to the ribosome, the peptidyl-tRNA is hydrolyzed, and the nascent polypeptide is released. The hydrolysis of GTP is necessary for the termination, although the exact point of hydrolysis in the process is not known. In prokaryotes, release factors RF1 and RF2 are codon specific and require the presence of RF3, which is needed for hydrolysis of GTP. The release factors have been identified but not purified in plants as yet.

1.7 Expression of Plant Organelle Genome

In plants, organelles such as chloroplast and mitochondria contain their own genome, which encodes polypeptides associated with the functioning of the respective genome. Both the genomes are semiautonomous, that is, most of the polypeptides necessary for the structure and function of the organelles are encoded by the nuclear genome. We will present an overview of the expression of chloroplast and mitochondrial genomes separately in the following section.

1.7.1 Expression of Chloroplast Genome

Chloroplast genome of higher plants is a circular molecule of 120 to 160 kbp and contains about 130 genes. About half of these gene products are involved in chloroplast genome expression (transcription/translation) and about 30 encode for the subunits of the five photosynthesis complexes that is photosystem I (PSI), photosystem II (PSII), cytochrome b6f complex, ATP synthase, and ribulose bisphosphate carboxylase/oxygenase complex. There are large intergenic regions in chloroplast genome and about 20 to 21 ORFs encode polypeptides of unknown functions. The parasitic plant, *Epifagus virginiana* has the smallest chloroplast genome (approx 71 kbp) since it does not contain genes related to photosynthesis. Unlike chloroplast genes of algal species, most chloroplast genes in higher plants are organized in clusters and are cotranscribed as polycistronic pre-RNA, which are then extensively processed into mono- and oligo-cistronic RNAs.

The transcription–translation machinery of chloroplast has a number of prokaryote-like features. For example, chloroplast ribosomes are 70S in size, chloroplast rRNAs and tRNAs are very similar in sequence to *E. coli* counterparts, and chloroplast mRNAs contain triphosphates at their 5′ ends and lack poly(A) tail. Most of the components of chloroplast transcription–translation machinery are not encoded by chloroplasts but are instead nuclear encoded. Therefore, information of the chloroplast genetic

system requires the coordinated expression of nuclear and chloroplastic genes. The upstream region of many transcription initiation sites on chloroplast DNA contains DNA sequence similar to *E. coli* "−10" and "−35" consensus sequences. These consensus (promoter) sequences are recognized by the plastid-encoded plastid (PEP) RNA polymerase and contain two conserved hexameric sequences, TTGACA and TATAAT with 17 to 19 nucleotides in between them. Analyses using genes with deleted or mutated promoter regions and *in vitro* transcription system have confirmed that "−10" and "−35"-like sequences are required for proper transcription of a number of genes. A DNA dependent RNA polymerase catalyzes the transcription of chloroplast gene, which is distinct from nuclear RNA polymerase. Multiple RNA polymerase activities have been found in chloroplasts. For example, in mustard chloroplasts, two distinct RNA polymerase activities (peak A and B) have been identified, both of which correspond to large multisubunit complexes. The genes encoding the core α, β, and β'-subunit homolog of the plastid RNA polymerase are encoded by plastid genome. On the other hand, several genes including some tRNA genes lack the usual prokaryotic promoter sequences in the region upstream of their transcription initiation sites, for example, the *rps16* gene possesses the "−10" motif but "−35" motif is missing. Other than "−10" and "−35" sequence NEP promoters (for nuclear-encoded chloroplastic RNA polymerases) are also reported. These promoters have a short, conserved sequence around the transcription initiation site. Multiple transcription initiation sites are known especially for the chloroplast genes *psbD, atpB,* and 16S rDNA. On the basis of biochemical evidence, it is now known that promoter recognition specific to PEP is conferred by three σ-like factors of 67, 52, and 29 kDa. These factors are nuclear encoded. In addition to PEP, there are nuclear-encoded RNA polymerases (NEP) in chloroplast. At least two NEPs are directed to the chloroplast in *Arabidopsis*. The NEPs resemble the phage-type single subunit enzyme related to the mitochondrial RNA polymerase. Thus, either chloroplast-encoded or nuclear-encoded RNA polymerases or both contribute to the transcription of individual genes. In general, it appears that the nuclear-encoded RNA polymerase transcribes genes for the chloroplast genetic system during the early stage of plastid development and subsequently transcription of photosynthesis-related genes is carried out by chloroplast-encoded RNA polymerase.

Though several chloroplast genes are monocistronically transcribed, most of the chloroplast genes of higher plants are co-transcribed. Polycistronic pre-RNA thus obtained consists of message for proteins or rRNA with related functions such as photosynthesis, transcription, and translation. Chloroplast polycistronic pre-RNAs are generally processed into many overlapping shorter RNA species. For example, *psbB* operon is transcribed from a bacterial type promoter as a polycistronic precursor (consisting of *psbB-psbT-psbH-petB-petD*). Two cis-splicing and multiple cleaving events take place to generate shorter RNA species from the polycistronic RNA. Many intermediate transcripts are generated during this process; at least 17 different species in spinach and 20 in maize have been observed. Processing ultimately generates monocistronic transcripts for *psbB* and *psbH* and dicistronic/monocistronic transcripts for petB-petD. It has been shown that processing often removes secondary structures that hinder translation of

genes when present in unprocessed polycistronic transcript, for example, psbA in *Arabidopsis*. A set of transcripts in chloroplast may also contain multiple 5′ ends. A different 5′ end for the same mRNA in the chloroplast provides a mechanism for translational control and differential stabilization of mRNA. In barley, an alternative transcript for rbcL accumulates, which has additional 35 nucleotides at the 5′ end. The additional sequence has high homology to the complementary sequence of the 3′ end of 16S rRNA. It is possible that formation of intermolecular complex between *rbcL* and 16S rRNA could hinder the translation of the *rbcL*.

Several chloroplast genes are interrupted by introns. In the tobacco chloroplast genome, 18 genes contain introns of 503 to 2526 bp in length, 6 for tRNAs and 12 for protein coding genes. Most introns can be folded into a characteristic, evolutionarily conserved secondary structure similar to that of the group II intron class. Chloroplast group II-type intron have conserved boundary sequences (5′-GTGYGRY···RYCNAYYYYTAY-3′), which are similar in part to those of nuclear pre-RNA introns. The intron of the gene encoding $tRNA^{Leu}$ (UAA) can be classified into the group I-type intron of fungal mitochondrial genes. In higher plant chloroplast, $tRNA^{Leu}$(UAA) is the only gene harboring a group I-type intron, but attempts to demonstrate self-splicing of its RNA *in vitro* have so far been unsuccessful. No self-splicing has been observed in group II-type introns. It is possible that RNA-protein interaction as in the case of nuclear transcripts is essential for splicing of chloroplastic transcripts.

Higher plant organelle mRNAs can be subjected to another posttranscriptional processing known as *RNA editing*. In chloroplast, it was first described with respect to the transcript of maize *rpl2* gene in which the AUG (Met) start codon is created by a C to U transition from ACG (Thr) codon. RNA editing in plastids seems to be an early step of pre-mRNA processing, which takes place independent of splicing and cleavage of polycistronic and monocistronic mRNAs. Transcripts, which are edited in one species, may contain the correct nucleotide at the DNA level in another species. For example, the *psbF* mRNA is edited in spinach plastids, changing a serine to a phenylalanine codon, whereas in tobacco a phenylalanine codon already exists at the DNA level. The simplest mechanism for RNA editing seems to be deamination of the C4 amide of cytosine to directly form a uracil residue; alternatively, a cytosine deletion and uridine insertion mechanism would accomplish the same task. The molecular mechanism that specifies the bases to be edited is still unknown, but flanking sequences are clearly important in the selection of editing sites.

The steady state level of chloroplast RNAs varies substantially for different genes, during developmental stages and in response to environmental stimuli, and fluctuates during circadian rhythms. In general, mRNAs encoding photosynthesis-related proteins accumulate at higher levels in chloroplasts from green tissues or during chloroplast development while levels are very low in plastids of nonphotosynthetic tissues, such as amyloplasts in roots and chromoplasts in fruits. The steady state level of chloroplast transcripts is regulated either by transcriptional activity or by stability of the particular transcript and is greatly influenced by light. It has been shown that often transcripts marked for degradation in the chloroplast are polyadenylated. Thus, polyadenylation of

transcripts renders them unstable. Thus, steady state levels of a particular transcript are regulated by factors governing the stability of the transcript rather than transcription rate in chloroplasts.

The stability of chloroplast RNAs varies from RNA species to species, depending on chloroplast development and environmental conditions. Most of the chloroplastic mRNAs contain invert repeat region in their 3′ UTR, which can fold to give stem-loop structure. These invert repeats were initially known to function as transcription terminators as in prokaryotes. However, it has been demonstrated that these structures probably act as processing signals rather than termination signals. Invert repeat-containing pre-RNA are processed in a 3′ to 5′ direction by 3′ exonucleases present in the transcription system, generating nearly homogeneous 3′ ends distal to the invert repeats. The processed 3′ ends form stem-loop structures, which bind to different nuclear-encoded polypeptides to provide stability to the transcript. These nuclear factors, also known as *RNA-binding proteins* (RNPs) are involved in splicing and/or processing of pre-RNA. In tobacco, five such proteins were isolated, which contain four domains necessary for binding to stem loop. These domains are a transit peptide, an acidic amino terminal domain and two conserved RNA binding domains. The RNA binding domain of approximately 80 amino acids belong to a superfamily, called *consensus sequence-type RNA binding domain* (CS-RBD) and is responsible for RNA binding. The nuclear-encoded RNA-binding proteins have been isolated from many different plants in the last decade and their role in binding to 5′ or 3′ UTR has been established. These polypeptides not only provide stability to transcripts after binding to 3′ UTR but also work as translational activators after binding to 5′ UTR of different genes present in chloroplast.

1.7.2 Expression of Mitochondrial Genome

Plant mitochondrial genomes are very large compared to human and yeast mitochondrial genome and extremely variable in size. The size ranges from 200 kbp in *Solanum tuberosum* to 2400 kbp in *Cucumis melo*. Much of the large size is the result of noncoding sequences that are present at multiple places in the genome. The mitochondrial genomes are much more complex compared to the chloroplast genome. The complexity of the plant mitochondrial genome can be represented by a single large circle designated the ''Master Circle''. The master circle contains repeated regions (in direct and/or inverted orientation) that are active in recombination. Recombination between direct repeats results in deletions. The deletions result in the production of ''subgenomic'' molecules. The abundance of each subgenomic molecule varies. Many appear to exist in very low copy number, and are called *sublimons*. Nuclear genes presumably play some role in regulating the relative abundance of various mitochondrial DNA configurations. *Zea mays*, has five different sets of repeats that are active in recombination. This results in a large number of different subgenomic molecules. If these contain active repeats, they can undergo further intra- and intermolecular recombinations. The result is a complex multipartite organization in which the same gene may be present in several different contexts. Given all this, it is not surprising that there is little or no conservation of gene order or physical maps among the mitochondrial genomes of the different plant species.

Even within a species, there is little or no conservation. Variation in the number of genes expressed in the mitochondria has been observed frequently. The *Arabidopsis thaliana* mt-genome of 366 924 nucleotides encodes 57 identified genes only. These are components of respiratory complexes, rRNA and tRNA genes, rRNA proteins, a group of proteins involved in cytochrome *c* biogenesis and 3 orfs common to most plant mitochondrial genomes. The genome of *Marchantia polymorpha* (the liverwort – a nonvascular plant) encodes more polypeptides than that of *Arabidopsis* – particularly ribosomal proteins. Only one-third of the mitochondrial genome has been shown to stably transcribe. The remaining appears to be nonessential, partly derived from chloroplast, partly from nucleus, and in part from the duplication of mitochondrial sequences. Extensive recombination has been shown to occur in mitochondria resulting in a lot of variation in the intergenic regions of the mitochondrial genome.

Most of the essential genes of mitochondria are expressed as monocistronic transcripts from individual promoters, for example, the *atp6*, *atp9*, *cytb*, *cox1*, *cox2* and *cox3* in most plants. The transcripts of most mitochondrial genes are found to be generally much larger than the actual coding regions of the genes. The change in size is because the transcripts contain extended noncoding 5′- and 3′-transcribed regions of several hundred nucleotides. Genes located closely show cotranscription invariably, such as 18S-5S-RNA genes or the *nad3-rps12* transcription unit. The transcribed spacer between 18S-5S rRNA varies among plants, ranging from just over 100 to over 500 nucleotides.

Inspection of the sequences at transcription initiation sites revealed several conserved sequences surrounding the first transcribed nucleotide. The minimal plant mitochondrial promoter (about 18 nucleotides in length) exhibits a short loose consensus sequence (CRTA) overlapping the transcription initiation site. *In vitro* experiments confirm the presence of a set of different types of promoter structure in plant mitochondria. Some of the promoters for protein coding genes differ from the consensus CRTA motifs, for example, ribosomal rRNA genes appear to be transcribed from a different type of recognition sequence in both monocots and dicots. In *Zea perennis*, such a nonconsensus promoter region was dependent on a nuclear gene product encoded by MCT gene, confirming that indeed distinct transcription cofactors act individually on these alternative promoter sequences. The mt-genome does not possess any gene for RNA polymerase; instead, a nuclear gene encoded polymerase is required. Recently, genes encoding mitochondrial-targeted, single subunit, phage T-7 type polymerases have been shown to be directed to mitochondria in *Arabidopsis* and maize.

The steady state level of mitochondrial transcripts may be regulated at the transcriptional level for the individual gene and/or by differential stability of particular transcript. While the higher transcriptional activity of the rRNA genes results in higher abundance of steady state RNA, the transcriptional activity of the protein-encoding genes may not correlate with the amount of the respective transcripts in the mitochondrial *in vivo* RNA population. RNA stability thus appears to play a major role in regulating steady state levels of RNA.

Several of the 5′-termini mapped for mRNAs as well as rRNAs in plant mitochondria cannot be labelled by *in vitro* capping experiments and may thus be derived from 5′-processing events. Some of

the *atp6* mRNA in maize mitochondria, for example, were found to initiate translation *in vitro*, although these could not be cap labelled. This suggests that inability to cap the RNA does not reflect that the processing has generated these. The 3′ termini of the plant mitochondrial mRNAs are not polyadenylated and thus require other means of sequence stabilization. Extensive 3′ processing is required because additional noncoding regions are usually included in the transcripts. Studies on many of the genes characterized in plant mitochondria suggest that 3′ UTR of mRNAs can fold into either single or double stem-loop structures. The secondary structure is most likely associated with the formation and/or stabilization of this RNA end but their role in transcriptional termination has not been ruled out.

RNA editing is a characteristic feature of plant mitochondrial genes. RNA editing modifies virtually every mitochondrial mRNA by C to U and also U to C modifications, which is required to generate correct open reading frames. RNA editing is thus an important regulatory step for the expression of genes. In wheat mitochondria, 19 mRNAs have been found edited at 364 positions. The least edited transcript to date is nad5 (5.5 editing sites per 1000 nucleotides), whereas the most edited is orf206 involved in the biogenesis of *c*-type cytochrome, (67.9 editing sites in 1000 nucleotides). Recombination studies suggest that sequences 5′ to an editing site are important for correct editing process. Analysis of other editing sites in the recombined maize *rps12* gene showed that at least 20 nucleotides 5′ to an editing site are required to specify editing. Analysis of RNA editing following the electroporation of mutated wheat mitochondrial *coxII* gene constructs into isolated mitochondria demonstrated that 16 5′ flanking nucleotides and six 3′ flanking nucleotides are required to specify an editing site. In general, at least 25 nucleotides 5′ to the editing site are critical to specify editing and some sites appear to have additional requirements for a limited number of 3′ nucleotides. While partially edited transcripts are sometimes translated in plant mitochondria, the corresponding proteins may fail to accumulate or accumulate but fail to assemble into protein complexes.

In summary, the transcription of plant genes is carried out by three different RNA polymerases whose activities are modulated by a diverse group of cis-acting regulatory sequences. RNA polymerase II is responsible for the synthesis of pre-mRNA. General transcription factors assemble into the initiation complex at the TATA box, which lies within 100 bp of the transcription initiation site of the gene. Pre-RNA transcripts must be processed by splicing, capping, and addition of poly(A) tail to produce a mature transcript, which must exit the nucleus to initiate translation in the cytosol. The chloroplast and mitochondrial gene expression is different from nuclear genes and requires completely different transcriptional and translational machinery.

2 Light Regulation of Gene Expression

Plants being sessile organisms adapt to various environmental stimuli to sustain their development. Light is probably the most important of these and forms the basis of plant and animal life. Almost every aspect of plant development is regulated by light and appears sensitive not just to light quality but also to light quantity and duration. Light drives photosynthetic reactions and these help in converting light

energy to chemical energy in the form of ATP and also provide reducing power for the synthesis of sugars, lipids, and amino acids. A byproduct of the reactions is evolution of oxygen, which sustains life. The fine-tuning of the response to light has been achieved by evolution of several light receptors that sense the different wavelengths and intensity. These include the phytochromes (for red and far red light), the cryptochromes, for blue light and UV light, and the phototropins. These photoreceptors help in mediating responses that lead to seed germination, hypocotyl elongation, growth, photosynthesis, photoperiodism, flowering, and so on. We shall be describing the role of these receptors in the regulation of gene expression in the following sections.

2.1 Phytochromes

These are homodimers of 124 kDa each containing a phytochromobilin as chromophore and a histidine kinase domain. They exist in two inter convertible forms – a Pr (inactive) form that absorbs red light and gets converted to Pfr (active) form by photoconversion and vice versa by absorption of far red light. At least five phytochromes (A–E) are known in *Arabidopsis,* which mediate responses to different wavelengths such as red, far red, the fluence of light (low and high irradiance), and the ratios of the red/far red lights. Phytochromes are present in the cytosol in their inactive (Pr) forms but are translocated to the nucleus upon photoconversion to their active (Pfr) forms. In the nucleus, they are localized to speckles where they are believed to interact with other nuclear proteins responsible for transcription. While phytochrome A (phyA) mediates far red light responses, phytochrome B (phyB) brings about responses to red light. Of all phytochromes, only phytochrome A is light labile.

2.1.1 Gene Regulation by PhyA Signaling

The phyA regulation of gene expression is most widely studied. PhyA is responsible for the high irradiance response of phytochrome action and helps in seedling de-etiolation, hypocotyl elongation, expansion of cotyledons, anthocyanin formation as well as perception of day length. Recent experiments have shown that the initial far red light responses mediated by phytochrome A probably occurs through activation of a group of master transcription factors within one hour of light sensing. These master regulators in turn activate a diverse group of transcription factors that result in extensive branching out of the response downstream leading to varied changes. Indeed, 10% of the total *Arabidopsis* genes are activated by phytochrome A. Of these about 50% are late acting and related to photosynthesis and general metabolism while about 44% are early responsive (activated within 1 h of light treatment) and are basically transcription factor genes belonging to different classes such as the zinc finger proteins, bZIP factors, basic helix–loop–helix proteins, Myb domain proteins, AP2 domain proteins, and so on. Among the main transcription factors, genes activated by phyA are the *PIF1* (*PHYTOCHROME INTERACTING FACTOR 1*), *HY5* (*HYPOCOTYL5*), *LAF1* (*LONG AFTER FAR RED LIGHT 1*), *TOC1 (TIMING OF CAB EXPRESSION 1), CCA1 (CIRCADIAN CLOCK ASSOCIATED 1), LHY (LATE ELONGATED HYPOCOTYL), CO (CONSTANS)*, and so on. Of these, PIF1, a bHLH protein, can bind both PHYA and PHYB and activate a subset of G-box (CACGTG) containing genes. The G-box has been found in

the promoters of several light responsive genes. HY5 is a bZIP type of factor that activates transcription of genes mainly in response to far red light and can bind the G-box in some light responsive genes such as *CHS* (*CHALCONE SYNTHASE*, involved in anthocyanin formation). Another transcription factor HYH, also a bZIP factor, can form heterodimers with HY5 *in vivo* but functions more in mediating blue light responses from cryptochromes. HFR1, a bHLH protein, is responsible for accumulation of *CAB* (CHLOROPHYLL AB BINDING PROTEIN) and *RBCS* (encoding the small subunit of RUBP carboxylase) transcripts. CCA1, LHY and TOC1, also activated by PhyA, are factors that regulate the circadian clock, while CO is known to be involved in flowering response.

2.1.2 Gene Regulation by PhyB Signaling

PhyB mainly senses red light and is responsible for red light mediated effects. Its main responses include the low fluence response promotion of seedling germination, inhibition of hypocotyl elongation, shade avoidance response (in which plants sense shade due to a low red:far red ratio and elongate to overcome the shade), inhibition of flowering, and so on. Signaling by phyB is mediated by PIF3, which binds to phyB in a light-dependent fashion. The other phytochromes (C, D, and E) also play a role in shade avoidance response and in flowering.

2.2 Cryptochromes

These are blue light-sensing flavoproteins with similarity to photolyases but without the DNA repair activity of photolyases. Two cryptochromes, CRY1 and CRY2 have been identified and are localized to the nucleus. The *c*-terminal portions of both the proteins are required for light signaling. The *c*-terminal can also interact with COP1 (a key negative regulator of light responses) and repress COP1. Cryptochromes have been shown to activate almost the same number of genes as red light and activate several transcription factors such as HYH. A ser/thr phosphatase has been shown to positively regulate blue light signal. While in animals cryptochromes form the central oscillator of the circadian clock, in plants they are responsible for light input to the clock. PhyA is also required for some cryptochrome responses.

2.3 Phototropins

These include PHOT1 and PHOT2 and are blue light and UVA sensing receptor kinases that control phototropism of stem and roots as well as chloroplast movement and stomatal opening. The phototropin signal is mediated possibly by NPH3 (NON-PHOTOTROPIC HYPOCOTYL 3) and RPT2 (ROOT PHOTOTROPISM2) since both contain BTB/POZ domains that are known to interact with transcription factors. Another transcription factor activated by these receptors is NPH4/ARF7 – an auxin response factor, indicating an interaction between phototropins and auxin signaling.

2.4 COP1 – A Major Regulator of Light Responses

In recent years, it has become increasingly apparent that plant responses to light and hormonal stimuli are regulated posttranscriptionally by protein degradation. The first evidence of the role of selective protein degradation came from the isolation of

the COP1 – an E3 ubiquitin ligase-like protein containing RING finger domains and WD repeats. COP1 localizes to the nucleus in the dark where it binds to transcription factors involved in light signaling such as HY5, HYH, and LAF, and promotes their ubiquitination and degradation via the proteasome. This prevents expression of light inducible genes in the dark. COP1 can also interact with CRY2, PHYB, and SPA1 and these interactions are believed to modulate its activity. In light, COP1 moves out of the nucleus into the cytosol while phytochromes move in. This allows light responsive transcription factors to transcribe genes. COP1 thus negatively regulates light responses and prevents light responses in the dark. Microarray analyzes have shown that expression of almost 30% of all *Arabidopsis* genes is influenced by COP1. COP1 interacts with the COP9 signalosome – believed to be the regulatory 19S subunit lid of the 26S proteasome. The COP9 signalosome has been shown recently to govern the degradation of regulatory factors involved in several responses such as those of auxins, JA (jasmonic acid), ABA (abscisic acid), gibberellins, flowering initiation, disease resistance, and so on.

2.5 Light Mediated Changes in Plastids

The major change that occurs upon receiving light is the conversion of the etioplasts to active chloroplasts. Phytochromes as well as cryptochromes are involved in this process of transformation. Absorption of light by the chlorophylls and carotenoids drives the photosynthetic electron transport and generates reducing power for synthesis of sugars. Since the whole process is sensitive to light, both nuclear and plastid genes have to be regulated in light. Most genes of the plastid, especially those involved in the light reactions, show a marked light induced upregulation of transcription or a light mediated increase in translation or stability of transcripts. Several light responsive elements such as the G-box, GT box, and so on, have been identified in the promoters of light responsive genes that bind accessory factors to drive light mediated transcription. Light quality and intensity also play a major role in regulating gene expression, for example, the psbD promoter has been shown to contain a light responsive element that is sensitive to red and blue light and responds to signals from both the cryptochromes and phytochrome A. Gene expression of light responsive genes is also regulated posttranscriptionally either through differential stability of transcripts or through differential translation.

2.6 Light Regulation of the Circadian Clock

The circadian clock of plants helps the plant in anticipating and preparing for the arrival of dusk and dawn and is thus closely linked to light input from photoreceptors. Light input from the photoreceptors (PhyA, PhyB, the cryptochromes, and possibly ZTL/FKF1/LKP1) entrains the clock with the environment making it sensitive to small changes in light duration. The clock itself consists of a feedback loop consisting of components that cycle between day and night. The central oscillator consists of two myb domain transcription factor genes *CCA1* and *LHY* along with *TOC1* and *ELF4* as primary components of the clock. *TOC1* is a gene that is responsible for activation of the two myb genes *CCA1* and *LHY*. These two genes in turn repress the transcription of the *TOC1* gene by binding on to an ''evening''

element (AAAATATCT) in its promoter. This results in cycling of the *TOC1* mRNA in such a way that *TOC1* mRNA and expression are low during the day but begin increasing late in the day. When levels of TOC1 increase, it begins transcribing the *CCA1* and *LHY* genes causing a peak increase in their levels in the morning. This represses *TOC1* during the day, which in turn affects (reduces) CCA1 and LHY levels in the evening. This results in a strong circadian rhythm where the expression of the *CCA1* and *LHY* are out of phase with *TOC1*. In addition, an F-box containing gene *ZTL* (*ZEITLUPE*) has been shown to be responsible for the degradation of TOC1 at night, thus creating a robust rhythm. Mutations in all the clock genes result in early flowering. The circadian clock has been shown to regulate the expression of several genes related to photosynthesis and pigment biosynthesis, which peak just before dawn in anticipation of light and those of lipid modification peak just before dusk and help in altering the desaturation levels of the lipids. Regulation of many of these genes involves the ''evening'' element in the promoter of these genes that are regulated by CCA1. Entrainment of the clock with the environment is brought about by the photoreceptors via PIF3 (binding PhyB), and other light sensing domain containing proteins such as ZTL, FKF1. Genes such as *ELF3* (*EARLY FLOWERING 3*) and *GI* (*GIGANTIA*) help in mediating the light input to the clock. PIF3 has been shown to upregulate both *CCA1* and *LHY*.

2.7 Light Regulation of Flowering Time

Another major effect of light is in determining the flowering time in some plants. This is known as *photoperiodism* and is based on the duration of light that triggers flowering. Plants can be classified as short day plants (SDPs, where flowering is initiated only below a critical day length), long day plants (LDPs, where flowering is initiated only above a critical day length) and day neutral plants that flower independent of the duration of day length. The ability to flower in a given day length is closely linked to the plant physiology and its adaptability to environmental conditions in that season that maximize the chances for proper seed set and survival.

At the genetic level, there are several genes involved in determining flowering time and floral initiation. The expression of the floral organ determinants in LDPs and SDPs is closely associated with light input to the circadian clock and regulation of its components by the photoreceptors, light quality, temperature. The circadian clock of the plant measures the time and day length and under favorable conditions genes responsible for initiating flowering are activated.

Phytochrome A and cryptochrome 2 are believed to promote flowering by activating floral pathway integrators and repressing phyB. On the other hand, phytochrome B as well as phyD and phyE repress flowering, with these effects occurring in a temperature-dependent fashion. PhyB repression is predominant at 22 °C while that of phyE is predominant at 16 °C.

In the last couple of years, the gene *CONSTANS* has been shown to be a major determinant in initiating flowering in both short day plants and long day plants. *CONSTANS* encodes a transcription factor with two B-box zinc finger domains and can directly activate *FT* (*FLOWERING LOCUS T*). Levels of *CONSTANS* transcript undergo a circadian rhythm and begin increasing during the day and reach

a peak at the end of day. However, levels of the protein begin accumulating only late in the evening during LDs. Another gene *FKF1* (*FLAVIN BINDING, KELCH REPEAT F-BOX CONTAINING*) has been shown to be responsible at least partly for the high levels of *CONSTANS* mRNA in light. By performing some elegant experiments with the use of mutants for flowering time as well as circadian clock it has been proposed that in long day plants such as *Arabidopsis*, the expression of *CONSTANS* mRNA and protein reaches a maximum at the end of the day and the coincidence of this expression with the light period in long days allows it to activate the flowering time gene FT. On short days, the peak of CONSTANS expression occurs in the dark and it is unable to activate FT. Moreover, there is a dark induced degradation of the CONSTANS protein by the proteasome brought about by ZTL. In light, the stability of the CONSTANS has been shown to be regulated by phytochrome A and cryptochrome 2, which stabilize it at the end of the day while phytochrome B is responsible for its instability and low levels during the mornings. These effects on stability are independent of the mRNA accumulation. Interestingly, in short day plants such as rice, the *CONSTANS* homolog *HD1* (*HEADING DATE1*) also shows a circadian peak with similar expression patterns, yet it brings about opposite effects as far as flowering is concerned. Experiments suggest that in short day plants, during the light phase, *CONSTANS* expression represses the expression of a transcription factor responsible for activation of *HD3a* (*HEADING DATE 3A*- or the homolog of FT in rice). This light mediated repression by CONSTANS of the transcription factor is activated by phytochrome. At night, expression of CONSTANS is high. This, along with the fact that phytochromes no longer activate it at night results in lack of repression of *HD3a* transcription and therefore the initiation of flowering. On long days, the CONSTANS protein remains activated by phytochrome and continues to repress transcription of *HD3a* resulting in no flowering.

2.8 Interaction of the Light Signal with Hormonal Pathways

Light signaling also interacts with other hormonal pathways to bring about plant development. Auxin has been shown to be involved in hypocotyl elongation and light regulates the expression of many auxin inducible genes. In fact, *IAA1, IAA9, PsIAA4,* and *AXR3*, have been shown to be phosphorylated by Phytochrome A. Degradation of some auxin regulated products occurs by the COP9 signalosome. Recently, a suppressor of *COP1, fin219,* was also shown to encode an auxin inducible gene. PhyB is known to promote seedling germination by activating gibberellin (GA) biosynthesis by activation of GA 3 β-hydroxylase. GA synthesis is responsible for the inhibition of hypocotyl elongation. Light also interacts with ethylene in mediating seedling development. Ethylene inhibits hypocotyl elongation in the dark but promotes it in light. Cytokinins are required during the greening process and application of cytokinins to plants grown in darkness causes de-etiolation, development of chloroplasts, and the expression of many light-regulated genes.

Light (both quality and quantity) thus affects several processes such as chloroplast biogenesis, entrainment of the circadian clock, flowering by photoperiodic responses, and general plant development

as well as several other aspects (not covered in this article) such as photosynthetic carbon fixation, carbon metabolism (interconversion of starch and sugars), nitrogen assimilation and so on. The responses and gene regulation are brought about by the action of different photoreceptors and their interaction with other hormone-signaling pathways as well as indirectly by the byproducts of photosynthesis such as reducing equivalents, sugars, ATP, and so on.

2.9 Nuclear-organelle Interactions

As has been previously described, plant cells contain chloroplasts and mitochondria, each with their own genomes. They perform the important functions of photosynthesis, lipid, and amino acid biosynthesis, respiration, and so on that are absolutely essential for the life of the plant. Large membrane-bound multiprotein complexes that contain polypeptides synthesized by both nucleus and the organelles bring about these processes. Almost 80 to 90% of the proteins located in the organelles are imported from the nucleus. Many genes, especially in the chloroplast, are transcribed as multicistronic mRNAs forming subunits of more than one complex that are differentially regulated by the environment or even showing tissue-specific expression as in the case of the *psbB* operonic genes. Gene expression of the organelles thus has to be tightly regulated so as to maintain the stoichiometry of the subunits in the multisubunit complexes. This is possible through a close coordination and communication between the nucleus and the organelles. Much of the transcription and translation of the organellar genes is controlled by the nucleus. The nucleus encodes at least three organelle directed RNA polymerases. One each is targeted at the chloroplast and the mitochondria respectively while the third has been shown to be directed to both the organelles. The three RNAPs are active at different times of plant development and undergo transcriptional regulation.

Besides synthesizing subunits for the photosynthetic and respiratory complexes of the organelles, the nucleus also exerts a great deal of control on the expression of the organellar genes and thus on their biogenesis. In recent years, many nuclear genes that are specifically required for the transcription, RNA processing, and stability, and translation of the organellar genes have been identified and characterized. Many of the regulatory genes are involved in gene-specific mRNA processing (both at the 5′ and 3′ ends) and translation such as in regulation of the *psbB* operon. The nuclear gene products of *NAC2, MBB1/HCF107, MCD-1* are necessary for processing, stability, and/or translation of the *psbD, psbB/psbH* and *petD* gene transcripts of the chloroplasts respectively, by acting at the 5′-end of the transcripts. Similarly, RB60 (a protein disulfide isomerase) and RB47 (a polyA binding protein member) are proteins that have been shown to bind the 5′ UTR of psbA and influence its translation. Secondary structures at the 3′ end of the plastid transcripts may also bind nuclear factors, for example, CSP41, CSP55, and CSP29 proteins have been shown to bind the stem loop and AU-rich element at the 3′ end of the *petD* pre-mRNA transcript in spinach. CSP41 has both RNA binding and endonuclease activities. Some gene products may control more than one process, for example, CRP1 seems to be independently responsible for *petD* transcript processing and *petA* translation in maize while the *HCF109*

in *Arabidopsis*, encodes a termination release factor that affects the expression of many plastid genes. Although the nucleus governs the expression of the bulk of the organellar proteins, there has to be compatibility between the nuclear and organellar genomes for a proper functional interaction to occur. Interactions between the whole nuclear plastid genomes have been studied in the subgenus *Euoenothera* of *Oenothera* and it has been shown that of the three nuclear and five plastid genomes that exist in this subgenus, only a few combinations exist in nature. Other combinations can be very disruptive leading to drastic dysfunction of the plastids resulting in nongreen tissues.

The effect of nuclear genes on mitochondrial gene expression has been studied mainly through the use of cytoplasmic male sterility (CMS) phenotype. CMS is a defect wherein plants are unable to produce functional pollen and are consequently male sterile. It has been shown that CMS results from incompatible nuclear-mitochondrial interactions and inheritance of the trait is non-Mendelian and maternally inherited. In several plants, CMS has been shown to occur due to expression of chimeric genes in mitochondria. These chimeric genes involve the fusion of a known mitochondrial gene with an unknown reading frame and this results in a novel open reading frame. Examples include the *T-urf13* gene in the CMS-T cytoplasm of maize (in which the coding portion contains the 3′ noncoding portion of *rrn26*), the *pcf* gene in petunia (containing portions of the *atp*9, *coxII* and *urfS*), the *pet1* gene in sunflower, *orf224* in Brassica (containing coding portions of *atp8* and *rps3*), *orf107* in sorghum (containing portions of *atp9*), and so on. In some cases, the expression of these chimeric genes may affect the normal expression or processing of the genes adjacent to them such as in the case of *orf224* in radish, which affects *atp6* expression lying downstream to it. In most cases, however, the chimeric protein may disrupt mitochondrial functioning by itself as in the case of TURF13 in maize and PVS in *Phaseolus*. This probably disrupts the energy processes especially in tissues requiring high mitochondrial activity such as the tapetum of male gametophytes. Restoration to fertility occurs when plants are crossed with restorer lines. These lines possess fertility restorer genes that are able to suppress the expression of the CMS genes. In recent years, fertility restorer genes or their loci have been identified for several CMS lines. Many of these belong to or contain genes that are part of a novel protein family termed the *PPR (penta-tricopeptide repeat) family of proteins*, for example, the restorer genes of *pcf* in petunia, *Brassica*, radish, and rice. Members of the PPR family are characterized by tandem repeats of 35 amino acids. Interestingly, this large family of proteins in *Arabidopsis* and rice, consisting of almost 400 members, is unique to plants and only one or two members have been identified in animals. Even more strikingly, almost two-thirds of these proteins are predicted to target the organelles indicating a predominantly organelle-specific function for this family of proteins.

2.9.1 Signaling Between Nucleus and the Organelles

Just as the nucleus controls the expression of the plastids, there is also a reverse signaling that signals the nucleus about the status of the chloroplasts and regulates expression of the nuclear genes. Experiments performed with the *gun* (*genomes uncoupled*) mutants in which LHCB expression is not repressed completely even

when plastid development is prevented by photo oxidative damage indicate that the *gun* mutants are affected in genes that encode products involved in the synthesis of tetrapyroles. Thus, much of plastid to nucleus signaling probably involves the chlorophyll precursors, Mg^{2+} protoporphyrin IX and protoporphyrin IX and a subunit of the Mg^{2+} chetalase. When levels of these precursors increase, they negatively regulate expression of nuclear genes such as *CAB* and *RbcS*. Expression of plastid and nuclear genes is also sensitive to redox regulation. This is not surprising considering that photosynthetic electron transport in light causes a change in the membrane potential as well as pH. The redox poise of the plastoquinone pool probably regulates LHCII kinase and is responsible for affecting nuclear gene expression of ferredoxin, and some PSI genes.

Thus, a close interaction and compatibility between all the three genomes, that is, the nuclear, plastid, and mitochondrial genomes is very essential and tight controls are exerted to help the plant in regulating the different process in the organelles and therefore plant development.

3 Hormonal Regulation of Gene Expression

Phytohormones are low molecular weight substances produced by plants that affect many processes throughout the development of plant life and its adaptation to the environment. They act specifically at very low concentrations (10^{-6} to 10^{-8} M) and usually trigger the effect after binding to specific receptors. Their effects are specific and not interchangeable. There are five classical groups of phytohormones: auxins, cytokinins, abscisic acid, gibberellins, and ethylene. Besides the five classical hormones, there are four more groups that regulate plant growth and are now considered as hormones. These are jasmonic acid, brassinosteroids, systemin, and oligosaccharides. Salicylic acid and nitric oxide are also involved in gene regulation during different stresses but so far they have been considered only as metabolites and not as hormones. This section will give brief information about five classical hormones, namely, auxin, cytokinin, gibberellin, abscisic acid and ethylene, and jasmonic acid and brassinosteroids. The receptors that have been identified so far and genes that are responsive to these hormones including responsive elements will be discussed. Systemin will be covered in the subsection of jasmonic acid.

3.1 Regulation by Auxins

Auxins play a crucial role in most of the major growth responses during plant development. They regulate various cellular processes such as cell division, differentiation, and cell extension, as well as other visible whole plant processes such as tropism (phototropism, gravitropism), root initiation, and apical dominance. The genes that are regulated by auxins within minutes of its application are referred to as *early or primary auxin response genes*. These genes are characterized as three different classes: Aux/IAAs, SAURs (small auxin up RNAs), and GH3s.

The aux/IAA genes are exclusively found in plants and belong to a multigene family with at least 27 Aux/IAA genes identified in *Arabidopsis* and other plants. The proteins encoded by these genes are small in size (about 20–35 kDa) with four highly conserved domains. They are localized in the nucleus and have a very high turnover

rate. These genes can also be induced even after treatment with cycloheximide (a eukaryotic protein synthesis inhibitor), indicating that these are kept inactive by a rapidly turned over repressor, which is somehow inactivated by auxins. There are some evidences that AUX/IAA proteins act as a repressor for their own transcription.

The SAUR genes, as the name suggests, encode small RNAs that are induced within 2 to 5 min of auxin exposure. They lack introns and encode small proteins of 9 to 10 kDA. At least 70 SAUR genes are known in *Arabidopsis*. Regulation of these genes is at the transcriptional level by auxin. These genes are not induced by cyclohexamide (protein synthesis inhibitor) but the treatment results in an increased accumulation of transcript probably due to the stabilization of SAUR transcripts. The role of the SAUR genes is not clear.

Auxin-regulated GH3 genes, like Aux/IAA and SAUR genes, were also identified through differential hybridization technique. Protein synthesis inhibitor does not affect GH3 transcripts, like those of SAUR and Aux/IAA. In *Arabidopsis*, the GH3 gene family consists of 19 members, which are divided in three subfamilies depending upon sequence homology and splicing patterns. Most of these show auxin induction. Interestingly, members of GH3 family, play a role in photomorphogenesis also. Two mutants *fin219* (*far red insensitive219*) and *fin19* of GH3 gene family have a role in light signaling. Another mutant *dfl1-D* (*dwarf in light*) has defective DFL1-D/GH3–6. In this mutant, GH3–6 transcript is highly expressed and shows dwarf phenotypes. Different GH3 genes may have specific roles in auxin and light signaling.

Another important family of genes is the PIN-formed (PIN) family that encodes auxin efflux carriers. These carriers are responsible for the active and directional transport of auxin and are required for tropical growth, regulation of root and shoot branching, and developmental patterning.

Promoters for different auxin responsive genes from all the three families have been cloned and studied. On the basis of studies on the different promoters, a 6-bp sequence TGTCTC has been identified as auxin responsive and is known as the *auxin responsive element* (ARE). Naturally occurring AREs are functional as simple elements or as composite AREs in which the ARE is functional only in combination with coupling or constitutive element. A trans-acting auxin responsive factor (ARF), which binds the TGTCTC of ARE, has been identified. At least 27 ARFs that express in almost all tissues are known in *Arabidopsis*. The ARF transcript is not auxin inducible. The N-terminal domain of ARF proteins has a DNA binding domain with specificity to ARE. The C-terminal domain is related to domain III and IV of AUX/IAA proteins, which probably facilitate heterodimerization. The central region of ARF functions as an activation/repression domain. ARFs that have a proline or a serine rich central region act as repressors (ARF1 and ARF2), whereas ARFs containing a glutamine rich middle region function as activators (ARF6, 7, and 8).

Regulation of gene expression by auxins is complex and knowledge about all the factors is limiting. A hypothetical model for auxin regulation has been proposed and according to this, at low auxin concentration ARF activators remain associated with AUX/IAA repressor through the carboxy terminal–dimerization domain resulting in repression of auxin responsive genes. At elevated levels of auxin, AUX/IAA repressor dissociates from ARFs, is bound

by the SCF^{TIR1} complex (an E3 ubiquitin ligase) and degraded by the proteasome pathway. This dissociation and degradation of AUX/IAA allow ARFs to bind to AuxRE to activate/derepress auxin responsive genes.

3.2 Regulation by Cytokinin

Plant hormone cytokinin controls cell division, shoot meristem initiation, leaf and root differentiation, chloroplast biogenesis, stress tolerance, and senescence. Cytokinin also plays an important role in shoot regeneration in plant tissue culture.

Analyzes of mutants in *Arabidopsis* suggest that the cytokinin-signaling pathway represents a two-component signaling system similar to bacterial two-component system. It involves a hybrid histidine kinase (AHK) as the cytokinin receptor and signal from AHKs to nuclear response regulators (ARRs) is transmitted through histidine phosphotransfer proteins (AHPs, which are about 12 kDa in size). Three genes that encode cytokinin receptors (*AHK4, AHK2,* and *AHK3*) have been identified in *Arabidopsis* and all of them are activated by exogenous cytokinin treatment. Two more genes, *CKI1* and *CKI2,* also exhibit cytokinin responses but are not activated by cytokinin and probably act through different perception mechanisms. Green fluorescent protein-based experiments provide evidence that AHPs shuttle from cytoplasm to nucleus in a cytokinin dependent manner.

There are about 22 ARRs in *Arabidopsis* and these are divided into two classes; type A ARRs have a response regulator and a short N- and C-terminal end and are cytokinin inducible, whereas type B ARRs are not affected by cytokinin but act upstream of type A ARRs to activate them. The type B ARRs have a C-terminal domain with a GARP motif that is distantly related to the Myb repeat of transcription factors and probably bind DNA as a monomer at the sequence 5′(A/G)GAT(T/C)3′. The type B ARRs have a central role in cytokinin signaling and overexpression of the C-terminal domain that contains the GARP domain and an acidic domain rich in P/Q residues, mimics cytokinin responses. The A-type ARR (ARR4, ARR5, ARR6, and ARR7) are induced within 10 min of cytokinin treatment. Expression of most type A ARRs is maximum in the roots. About 823 upregulated and 917 downregulated genes have been identified in *Arabidopsis* following cytokinin application. While some cytokinin genes such as *AHK4* are expressed in the globular embryo and play a role in embryonic cell proliferation, vascular morphogenesis, and root meristem activity, other genes such as *ARR2* regulate genes that are involved in synthesis of components of mitochondrial complex I and play a role in pollen formation and sporogenesis. *ARR4* can interact with phyB and stabilize it and it also interacts with auxin responsive genes such as *AtDBP1* and *AtDBP2* indicating the involvement of cytokinin in light and auxin effects. Cytokinins also regulate expression of some ribosomal proteins like S14, S16, L13a, and L30 and hence these are probably involved in translational processes as well besides regulating at transcriptional level.

The hypothetical model for cytokinin signal transduction suggests that cytokinin signal is perceived by AHKs. AHKs initiate a signaling cascade through phosphorelay and shuttle AHP to nucleus. Activated AHPs interact with repressed ARRs in the nucleus and release their repression. The derepressed ARRs bind to multiple cis-elements in the promoters of target genes.

It has been recently suggested that the increase in endogenous cytokinin is perceived by a two-component system and transduced into the nucleus by MAP-kinase signaling and translated into a response by inducing WRKY transcription factors, which later activate downstream genes.

3.3 Regulation by Gibberellins

Gibberellins (GAs) influence the growth and development of the plant and are especially important in leaf expansion, stem elongation, seedling starch reserve hydrolysis, and flowering. The knowledge about GA function comes mainly from studies carried out in *Arabidopsis* and on the barley seed aleurone layer. Little is known about GA perception, downstream-signaling components and GA responsive genes. DNA microarray analyses have led to the identification of 138 upregulated and 120 downregulated GA responsive genes. GA has been shown to activate expression of the expansin gene in rice that causes internode expansion allowing rice plants submerged in floods to rise above the water. The α-amylase gene, responsible for starch breakdown in the aleurone layer, is another important GA-regulated gene. These, as well as other genes encoding hydrolytic enzymes, are rapidly activated in the cereal aleurone layer in response to GA. A Myb factor, GAMYB, has been shown to bind to the amylase promoter and activate its transcription as well as that of other hydrolytic enzyme genes. Another gene, *HRT* (*HORDEUM REPRESSOR OF TRANSCRIPTION*), encodes a zinc finger repressor that binds to the promoter of the amylase gene and represses transcription. The D1 gene, that encodes a putative α-subunit of the hetero-trimeric G-protein, has been shown to positively regulate GA responses.

Studies carried out on *Arabidopsis* mutants (dominant and recessive) indicate that GA signal transduction pathway is activated by inhibition of the repressor protein GAI (GA INSENSITIVE) and RGA (REPRESSOR OF *GA1-3*). These are homologs and function as nuclear transcriptional regulators. GAI and RGA possess a DELLA motif in their N-terminal domain (hence referred to as *DELLA proteins*) and belong to the large GRAS family in *Arabidopsis* that act as transcriptional regulators. Five GAI/RGA related genes (*GAI, RGA, RGL1, RGL2,* and *RGL3*) are present in *Arabidopsis*. Deletion of the 17 amino acid residues within the DELLA sequence in RGA (rga-Δ17) produce a constitutively active repressor that is not inactivated by GA. Apparently, this deletion makes mutant protein stable and resistant to GA induced degradation. Probably, the N-terminus of DELLA protein is a regulatory domain, which senses the GA signal, whereas the C-terminus functions as the repressor of GA signaling. DELLA proteins repress GA signaling in other plant species and GA-insensitive dwarf plants have been identified in maize (*D8*), rice (*slr-1*), barley (*sln1-d*), and grape (*Vvgai1*). In all these mutant species, the DELLA proteins are altered in the N-terminal region. The information on rice suggests that it contains a single DELLA protein gene and knocking out this gene results in a taller phenotype. This dramatic change, upon knocking out a DELLA protein gene, is not seen in *Arabidopsis* due to functional redundancy amongst its five DELLA members. Other repressors of GA signaling include SPINDLY (an O-linked *N*-acetylglucosamine transferase) and possibly SHORT INTERNODES while positive regulators include the *SLEEPY1*

gene, that encodes an F-box protein involved in degradation of the GA repressors. PICKLE, a CHD3 chromatin-remodeling factor, that suppresses embryonic differentiation in *Arabidopsis*, is also likely to be a positive regulator.

GA also plays an important role in flowering and this is achieved by direct activation of the floral meristem identity gene, *LEAFY*. An 8-bp cis-acting element, necessary for GA dependent expression, has been identified in the LEAFY promoter. However, this 8-bp element is not common for all GA responsive genes and some other unidentified elements regulate GA response. In potato, *PHOR1* (*PHOTOPERIOD RESPONSIVE 1*) has been identified as a GA upregulated gene that may function as an E3 ubiquitin ligase to degrade GA repressors. This gene is also regulated by photoperiodic responses and thus provides an evidence for interaction between GA and light signaling. It is interesting that many GA downregulated genes also have ABA responsive elements in their promoters indicating cross talk between GA and ABA.

3.4 Regulation by Abscisic Acid

Abscisic acid plays a role in various processes such as plant development, seed dormancy, germination, and stomata closure. It also has a major role in abiotic stresses such as drought and salt. At a cellular level, it modulates cell division and cellular responses to biotic and abiotic stresses.

Genome-wide gene expression profiling in *Arabidopsis* reveals that at least 1300 genes are either up- or downregulated by ABA. More than 90% of these genes showed impaired regulation in the *abi1-1* mutant (which encodes protein phosphatase2C) indicating an important role for this enzyme in ABA signaling. Besides transcription factors such as VIVIPAROUS/ABA INSENSITIVE3 and the bZIP and AP2 type of transcription factors that mediate ABA gene regulation, ABA also induces the expression of the LEA (LATE EMBRYOGENESIS ABUNDANT) class of proteins during seed formation and abiotic stress. These proteins are required for protection against desiccation. Many ABA-regulated genes contain ABA responsive elements (ABRE) consisting of ACGT-containing G-box. However, optimal ABA responsiveness requires a second GC rich coupling element (CE), which is similar to ABRE and approximately 30 bp downstream of the main ABRE. This coupling element can bind AP2 domain type of transcription factors. Other cis-elements that bind Myc and Myb domain proteins have also been reported.

Gene regulation during seed and early seedling development is brought about by the bZIP factor *ABA INSENSITIVE5* (with 9 nine members in *Arabidopsis*), while the bZIP factor AREB/ABF (ABRE BINDING FACTOR) acts later during development. Both are activated and stabilized by phosphorylation by SNF1-related protein kinases, ABA-INDUCED PROTEIN KINASE1 (PKABA1)/ABA ACTIVATED PROTEIN KINASE (AAPK). The factors activate transcription by binding the ABRE in the promoters of several genes. ABI5 can also interact with ABI3 to enhance transcription of some of these genes. When the ABA signal is to be attenuated or abolished, a protein ABF (ABI5 BINDING PROTEIN) binds ABI5 and targets the dephosphorylated form of ABI5 for degradation by the proteasome.

Another regulator of ABA responses is the homeodomain leucine zipper (HDZip) protein HOMEODOMAIN PROTEIN 6

(AtHB6). This protein binds to an AT rich cis-element and interacts with ABI1. Nuclear localization of this protein desensitizes guard cells and seeds to ABA. ABA also controls gene expression at the posttranscriptional level by downregulating expression of ribosomal proteins and upregulating genes involved in proteolysis. Posttranscriptional control is also evident in the form of dephosphorylation of the carboxy-terminal domain of RNA polymeraseII by the genes *AtCPL1* and *AtCPL3* (*CARBOXY-TERMINAL DOMAIN PHOSPHATE-LIKE1* and *3)*, which results in downregulation of ABA inducible genes. In contrast, phosphorylation of AKIP1 (AAPK INTERACTING PROTEIN1) by AAPK targets AKIP1 at mRNAs of dehydrin, allowing their translation in the guard cells. Another protein ABA-HYPERSENSITIVE1 (ABH1) encodes a subunit of the cap-binding complex and participates in several RNA processing events that may affect transcripts that limit ABA-signaling events.

ABA response regulators comprise G-proteins, protein phosphatases, and protein kinases of the Ca^{2+} dependent protein kinase (CDPK) and SUCROSE NON FERMENTING protein (SNF-1)-like groups. The RHO-like small G-protein ROP10 (as well as ROP2 and ROP6) negatively regulate ABA mediated stomatal closure, germination, and growth inhibition. This protein mimics the role of small G-protein RAS in the mitogenic responses of mammals. These proteins are also associated with increased H_2O_2 production because of their activation of NADPH oxidase. Other negative regulators include four protein phosphatases (PP2Cs) ABI1, ABI2, AtPP2CA, and AtP2CHA found in *Arabidopsis*. However, these are transcriptionally upregulated by ABA. ABI2 mediates its action by binding to CIPK15, which is required for ABA action, and negatively regulates the signal relay.

Cellular responses to ABA vary in different cell types and it is possible that there exist separate ABA-signaling pathways in different cells. No receptors have yet been identified for ABA. ABA regulates plasma membrane and ion channel activities and it is possible that ABA interacts directly with transport proteins or metabolic factors. Studies on stomatal closure suggest that cytosolic Ca^{2+} mediates stomatal closure and Ca^{2+} channel activation is ABA mediated. Phospholipase C (PLC) and phospholipase D (PLD) are activated during ABA signaling and generate IP3 and phosphatidic acid as second messengers. Studies on transgenic tobacco plants with reduced PLC expression in guard cells reveal impairment of ABA related activities in both mediation of stomatal closure and inhibition of stomatal opening.

The pH and redox status of a cell are also crucial in regulating ABA signal transduction. H_2O_2 and nitric oxide (NO) concentration increase before ABA-induced stomatal closure. The redox signals provided by varying concentrations of H_2O_2 and NO are characterized by short biological half-life. Studies on nitrate reductase–deficient double mutants (*nia1* and *nia2*) indicate strongly impaired NO production and stomatal closure in the presence of ABA. Results also infer that NO is active upstream of Ca^{2+} and NO and H_2O_2 activate inward rectifying Ca^{2+} channel. ABA signaling downstream of Ca^{2+} is negatively regulated by protein phosphatase ABI1 and ABI2.

3.5 Regulation by Ethylene

Ethylene affects all the major developmental processes in plants starting from

germination, flower and leaf senescence, fruit ripening, abscission to programmed cell death. It also plays an important role in various biotic and abiotic stresses. Ethylene causes exaggeration of the apical hook, shortening and thickening of the hypocotyls, and inhibition of root growth in dark grown seedlings of *Arabidopsis* – a phenomenon known as *triple response*.

Ethylene is perceived by a family of five receptors (ETR1, ETR2, ERS1, ERS2, and EIN4) in *Arabidopsis*, which share similarity with the bacterial two-component signaling system. These receptors show redundancy in function and act as negative regulators of ethylene responses. These contain an amino terminal ethylene binding domain (sensor domain) that binds ethylene via a Cu^{++} and a C-terminal histidine kinase domain whose activity is not necessary for receptor function. It has been suggested that this domain in ethylene receptors is probably required for localization, protein stability, and/or interaction with other functions. Besides *Arabidopsis*, a large number of studies have been carried out in tomato to understand the role of ethylene in development and in fruit ripening. In tomato, six ethylene receptors (LeETR1–6) have been identified. These are very similar to those in *Arabidopsis*. Most of the information available on tomato ethylene signaling is through *NEVER RIPE* (*Nr*) and *ripening inhibitor* mutants that are affected in tomato fruit ripening.

The receptors are localized in endoplasmic reticulum. The ethylene signal is transmitted by the ethylene receptors to CTR1 (an Raf-like MAPKKK-like protein). Ethylene signal is then transduced downstream via a signal transduction cascade that involves MAP kinases to finally activate a series of transcription factors that are specific for different genes. The signaling is unique in the sense that while the first two components of the signal cascade, that is, ethylene receptors and CTR1 are negative regulators, the downstream components (MAPKK onwards) are positive regulators of the signal. Also, it couples a two-component system with an MAP kinase cascade. In the absence of ethylene, the receptors are in an active state and interact with N-terminus of CTR1, which then represses the downstream ethylene responses. Interestingly, the MAPK cascade genes involved in ethylene signaling have also been shown to play a role in biotic stress related ethylene release and salt stress signaling.

In *Arabidopsis*, the EIN3 family has been identified as containing transcription factors, which mediate all ethylene responses. There are six members in the family but only EIN3 and EIL1 play a major role in ethylene responses. The rest of the members (EIL2–5) play roles in specific developmental stages or tissues. It is speculated that these may function in other pathways, which are not ethylene dependent. Other plant species like tomato, tobacco, and mung bean also have orthologs of EIN3. The EIN3 family of transcription factors is regulated by ethylene through a posttranscriptional mechanism that involves protein degradation mediated by the ubiquitin/proteasome pathway. Interestingly, glucose enhances EIN3 degradation through functional glucose sensing hexokinase (AtHXK1) indicating an interaction between ethylene and sugar signaling.

Genetic and biochemical studies have identified an ethylene responsive gene *ERF1* as a first target for EIN3. *ERF1* binds to 11 bp GCC-box element in promoters of many ethylene and pathogen induced genes. ERF1 belongs to a large

AP2/EREBP family (ETHYLENE- RESPONSE ELEMENT BINDING protein), which is exclusive to the plant kingdom. This family consists of 144 members in *Arabidopsis* and is characterized by the presence of a conserved AP2 domain of 58 to 59 amino acids. This large family is divided into two subgroups: The AP2-like subfamily consists of two AP2 domains and includes genes such as *APETALA2, AINTEGUMENTA* (*ANT*) and *GLOSSY15*. These genes are involved in seed development and floral organ specification. The subfamily EREBP has a single AP2-like domain and includes ERF1, ERF2, ERF3, and ERF4 from tobacco, and AtEBP, TINY, CBF1, OsEBP89, and so on. ERFs can act both as activators and repressors of gene expression. ERFs that repress gene expression contain an additional EAR (ERF-associated amphiphilic repression) motif that is also present in many zinc finger repressor proteins. These repressor-ERFs function mainly in response to biotic and abiotic stresses. Important targets of the ERFs include genes such as chitinase, β-1,3-glucanase and pathogenesis related proteins that play a role in defence. In addition, ethylene induction of β-1,3-glucanase also plays a role in seedling germination, mobilization of storage reserves in the endosperm, pollen development, and so on. Studies carried out on ethylene-regulated genes involved in fruit ripening and senescence have so far not detected GCC-box. These genes, instead, have conserved octanucleotide sequence PERE (ATTTCAAA) that confers ethylene sensitivity. This sequence is also present in E4 and E8 promoters of two tomato fruit specific genes. In a recent experiment, 624 genes out of 22 000 studied, were found to be regulated by ethylene in the seedlings of *Arabidopsis*. Other fruiting plants such as tomato, banana, peach, apple, and so on, are likely to possess many more genes regulated by ethylene due to its role in climacteric fruit ripening. Ethylene can also interact with JA in defense and wounding responses and these effects are mediated by ERF1. It was recently shown that ERF1 acts as a common downstream component for the two hormones and blocking either pathway by genetic means prevents ERF1 induction by ethylene and JA, either alone or in combination.

3.6 Regulation by Jasmonic Acid

Jasmonic acid and its derivatives affect a variety of processes in plants such as pollen maturation, root growth, tendril coiling, fruit ripening, biotic and abiotic stresses, and defense against insects. The biochemistry of JA synthesis is well known but its perception and receptors are not yet very well understood. The current information for JA signaling is mainly available through *Arabidopsis* and tomato but with several discrepancies.

JA signaling is induced by osmotic stress, wounding, drought, and various elicitors (chitins, oligosaccharides, etc.). Transgenic studies reveal that in tomato a MAP kinase, WIPK, is required for wound-induced JA biosynthesis. In *Arabidopsis*, MPK4 is responsible for mediating JA responses indicating that different MAP kinases act at different points in the JA pathway. Insect attack on tomato leaves activates systemic JA synthesis through a small polypeptide systemin, an 18-amino acids long peptide that has been identified as a signal substance for systemic activation of defense genes. It is produced from a larger precursor and is transported by the vascular system of the plant. Systemin and oligosaccharides use a similar transducer although the

oligosaccharide effect is local, whereas systemin leads to systemic effects.

Microarray analyses suggest that JA activates at least five genes for its own biosynthesis. Transcriptional activation of these five genes (*DAD1, LOX2, AOS, OPR3,* and *JMT*) occurs at the site of JA biosynthesis indicating that JAs are synthesized locally in response to stress. Till date, no receptor has been identified for JA signal transduction. Different studies carried out in *Arabidopsis* indicate involvement of two different pathways in JA signal transduction. One pathway, responsible for defense responses, recognizes OPDA (12-oxophytodienoic acid) or JA. The other pathway recognizes only JA for pollen maturation. Screening of various mutants for JA receptors identified only *COI1* (*CORONATINE INSENSITIVE 1*) and *JAR1* (*JASMONATE RESISTANT1*) genes. But the proteins encoded by these genes do not show homology to any plant receptor protein. So far two genes that mediate the JA signal transduction have been identified. The first one, *ERF1*, is common to both ethylene and JA responses during pathogenesis. The other *AtMYC2* differentially regulates two groups of genes; those related to defense responses are repressed by it while those related to JA mediated systemic responses to wounding are activated by it. Interestingly, *ERF1* has the opposite effect on these groups of genes. Thus, responses of ethylene and JA can be integrated during plant defenses but are antagonistic during the wound response. JA can also act synergistically with ABA in inhibiting seed germination and has a close interaction (both positive and negative) with salicylic acid.

Like other hormones, regulation of JA responsive genes occurs through proteasome-mediated degradation. Studies on *coi1-1* mutant, which is insensitive to coronatine (a structural analog of JA), reveal that this mutant fails to express JA-regulated genes such as *VSP* (VEGETATIVE STORAGE PROTEIN), *Thi2.1* (THIONIN 2.1) and *PDF1.2* (PLANT DEFENSIN1.2). The *COI1* gene encodes F-box protein, which functions as a receptor, recruiting regulatory proteins as a substrate for ubiquitin mediated destruction. Immunological studies suggest that COI-1 forms an SCF complex, which degrades other proteins by proteasome system. Only one transfactor, ORCA3, is known to be involved in JA responses. This transcription factor has a JA responsive APETALA2 (AP2) domain. Its overexpression results in induced expression of several genes for metabolite synthesis. ORCA3 binds to JA and elicitor responsive elements (JERE) in the promoters of JA responsive genes. The JA responsive element in the promoter of plant defensin1.2 (PDF1.2) also contains GCC-box, which is required for ERF1 binding.

3.7 Regulation by Brassinosteroids

Brassinosteroids (BR) are plant steroids that act as plant hormones and brassinolide (BL) is the most bioactive form of BRs. Brassinosteroids have growth-promoting activity and affect leaf bending, cell elongation, cell division, proton pumping, and membrane polarization. In addition to this, these steroid hormones also affect sensors and stress responses. BR-deficient mutants show dark green dwarf phenotypes in the absence of light suggesting potential interaction between BR and light-signaling pathways. Inhibitors of BR biosynthesis (Brassinozol) also generate phenotypes mimicking those of BR-deficient mutants.

BL is perceived by putative receptors BRASSINOSTEROID INSENSITIVE 1(BRI1), which is a plasma membrane localized leucine rich repeat (LRR) receptor kinase. BRI belongs to the specific family of receptors, which like kinases, have Cf-9, TOLL, LRR, and CLAVAT2 receptors. The extracellular portion of BRI is required for BR dependant activation of the intracellular Ser/Thr-specific kinase domain. Interestingly, a tomato receptor kinase SR160LRR identified as the receptor of peptide hormone systemin is identical to BRI1. This indicates that brassinosteroid and systemin share one receptor for signaling pathway.

BRs inhibit the genes required for their own biosynthesis. The transcription of CPD gene (encoding C-23 steroid hydroxylase CYP90A1) is downregulated by BL and other bioactive BRs. The BRI-5 mutant has impaired BR perception and shows derepressed expression of CPD. Besides BR biosynthetic genes, BL also negatively regulates the transcription of a number of genes. The BR-activated gene, *BRUI*, identified in soybean encodes xyloglucan endotransglycosylase. Brassinolides also induce xyloglucan endotransglycosylases (XETs) in several plants and this XET induction correlates with cell wall loosening during BL-induced growth responses. The other important genes that are BR inducible include cyclin gene *CycD3* (involved in cell cycle) and CDC2b cyclin dependent kinase in the absence of light. A homolog of animal translation initiation factor eIF_3 (TRIP) has been found to be upregulated by BR in *Arabidopsis* and can establish a link between BL-signaling and developmental pathways controlled by the homolog of translation initiation factor.

At present, all the components of BR signaling have not been elucidated and a hypothetical model for BR signaling has been proposed. According to this model, BRI1 is the receptor for signal perception. BR promotes autophosphorylation and activation of BRI1 triggering downstream responses by its binding to BRI1. KAPP-like protein phosphatase has been suggested to modulate BRI1. BRI1 deactivates the cytoplasmic GSK3/SHAGGY-like BIN2 kinase, which is a negative regulator of BR signaling and it phosphorylates downstream components BES1 and BZR1 and prevents their translocation to the nucleus. A MAPK cascade may come into play and activate transcription factors that control activation or repression of BR-responsive genes. Alternately, it is possible that BRI1 directly phosphorylates transcription factors and other signaling components like TRIP modulating diverse cellular responses.

3.8 Control of Gene Expression by Proteolytic Degradation:Role of the Proteasome

In recent years, proteolyses of key repressors or activators of response mediators in hormonal regulation, disease resistance, flowering, and light regulation has been shown to be a very effective means of controlling responses. It involves the polyubiquitination of proteins marked for degradation and their transfer to the proteasome by the SCF complex proteins. The F-box proteins that have specificity for the target protein as well as the SCF proteasome play an important role in this process. More than 600 F-box proteins are believed to be present in *Arabidopsis*. In hormonal responses, degradation of repressors of auxin, gibberellins and JA signaling, and activators of ethylene and ABA responses provide a rapid means to regulate responses. Repressors for auxin signaling such as the Aux/IAA proteins

are targeted for degradation by the SCF^{TIR} complex, while the DELLA motif containing repressors of GA signaling, RGA and GAI, are degraded by the proteasome by SCF^{SLY}complex. On the other hand, ethylene signaling is prevented in the absence of ethylene by the degradation of EIN3 – a transcription factor that activates ERFs, while ABA signaling in the absence of ABA is prevented by degradation of the bZIP factor ABI5. This is similar to the prevention of light responses in the dark by degradation of light responsive transcription factors by COP1.

3.9 Cross Talk Between Phytohormones

Modern research on the classical plant hormones is providing interesting information about the interaction between these regulatory components. The cross talk between these hormones influences plant growth and development.

Ethylene and abscisic acid interact with each other during root elongation and seed dormancy. Mutant analyzes of *era3* (*enhanced response to ABA3*) reveal that this gene is allelic to ethylene insensitive *ein2* mutant. Increased seed dormancy of mutant *ein2–45* is counteracted by ABA insensitive mutant *abi3–4*. The double mutant *abi3–4ein2–45* germinates faster than wild type indicating a strong interaction between ethylene and ABA signal transduction pathway. In contrast to seed dormancy, ethylene, and ABA, both inhibit root elongation. ABA inhibits root growth more effectively if ethylene concentration is low indicating that ethylene negatively regulates root responsiveness to ABA. It has been hypothesized that ABA acts through ethylene signal transduction and both of these hormones compete with each other to activate that pathway.

Auxins and GA promote stem elongation and normal levels of auxins are required to maintain the normal levels of GAs. Auxin upregulates *LE* mRNA, which encodes the enzyme involved in GA_1 biosynthesis. Different studies made on pea plants suggest that auxin is transported to elongating internodes from apical buds. There it induces the transcription of *LE* mRNA and downregulates the expression of PsGA2ox1, which encodes an enzyme that catalyzes the deactivation steps of GA_1 to GA_8. Microarray studies also indicate that GA affects ethylene biosynthesis and its responses. Auxin and ethylene affect GA-regulated root and hypocotyl growth by modifying the stability of RGA. Other examples of phytohormone cross talk have already been mentioned in the text. The SCF E3 ubiquitin ligase mediated protein degradation plays a central role in each of the hormones (auxin, ethylene, ABA, GA, and JA) signal cascade and it is possible that this system provides the molecular link to the phytohormone cross talk.

JA signal pathway interacts with ethylene signal pathway in the expression of defense response and in development. It also interacts with auxin and salicylic acid signaling. Brassinosteroids (BR) interact synergistically with auxins in hypocotyls elongation. Several studies indicate that BR-induced effects are mediated via auxin, whereas BR alters the levels of endogenous auxin or enhances the sensitivity to auxin. BR upregulates many early auxin-inducible genes suggesting overlap of auxin and BR-regulated genes.

This cross talk between different hormones is indicative of the fact that possibly fewer elements are necessary for overall hormonal regulation. Probably, due to this cross talk, a single hormone is able to cause different responses in different

organs by interacting differently with other hormones that are present.

4
Gene Regulation During Stress

Plants are sessile organisms and are constantly exposed to changes in environment conditions. They are exposed to biotic stresses like pathogen or fungal attack, insect attack, herbivores, and wounding. Plants are also challenged by abiotic stresses like salt, drought, and cold. Plants have evolved various mechanisms to overcome the damage caused by stress. The response to environmental change is usually rapid and involves regulation of various genes. Hormones like ABA and ethylene and metabolites like salicylic acid, nitric oxide, and reactive oxygen species have been shown to play an important role during these stresses evoking various gene responses.

4.1
Regulation during Abiotic Stress

Environmental stresses such as drought, cold, and salinity, induce several genes that provide stress tolerance to plants. The genes induced by abiotic stresses have been classified into two major groups. One group encodes proteins that directly protect plant cells against stresses (such as heat shock proteins, LEA proteins, ROS scavenger proteins like SOD, catalase etc.), whereas the proteins encoded by the other group regulate gene expression and signal transduction. Many stress inducible genes include those that encode enzymes involved in phospholipid metabolism, various protein kinases like MAP kinases, Ca^{2+} dependent kinases, receptor-like kinases and histidine kinases.

Plants undergoing abiotic stresses in general face dehydration and hence almost 50% of the genes activated by these stresses such as drought, salinity, or ABA treatment are common. In contrast, only 10% of the genes are common to cold stress. Many transcription factors have been found to be stress responsive. These include members of DRE binding protein (DREB), ethylene responsive factor (ERF), the MYB family, the zinc finger family, the homeodomain transcription factor family and the WRKY family. Studies on the proline dehydrogenase gene (*ProDH*), which is rehydration inducible, reveal an important cis-acting element ACTCAT, which is found in many rehydration inducible genes. The gene *RESPONSIVE TO DEHYDRATION 29 (RD29A,* also known as *COLD REGULATED 78* or *COR78 / LOW TEMPERATURE INDUCED* or *LT178*) is responsive to drought, salt, and cold. The promoter of this gene has two distinct cis-acting elements; one DRE/CRT (*d*ehydration *r*esponsive *e*lement/*C r*epea*t*), responsive to drought, salt, and cold and the other ABRE, which is ABA responsive element. DREB proteins bind to DRE/CRT elements and are classified in two groups – DREB1 and DREB2 that are induced specifically by cold and drought respectively. Transgenic studies show that drought and salt trigger both ABA-dependent and ABA-independent pathways, whereas cold signal is transmitted through ABA-independent pathway because low temperature does not induce accumulation of ABA in plants. Homologs of DREB1 and DREB2 have also been found in rice and function similar to *Arabidopsis* homologs in stress responsive–gene expression and stress tolerance. Several drought-inducible genes are not activated by cold or ABA. These genes include *ERD1* (*EARLY RESPONSIVE TO*

DEHYDRATION1), which encodes a Clp protease regulatory subunit. This *ERD1* gene is also upregulated by senescence.

Recent studies indicate that Ca^{2+} acts as a second messenger in abiotic stress and ABA response. According to present hypothesis, Ca^{2+} transmits the stress signal downstream by interacting with protein sensors. The Ca^{2+} sensors such as calmodulin, calcineurin B-like (CBLs) and calmodulin domain protein kinase (CDPK) bind Ca^{2+} and induce conformational change. CBL and calmodulin are small Ca^{2+} sensors, which function by interacting with and regulating the function of their target genes. CBL protein interacts with a specific group of protein kinases called *CBL interacting protein kinases* (CIPKs). There are evidences that *CaM* gene functions as a negative regulator of stress gene expression, whereas CBL1 acts as both a positive and a negative regulator in different signaling pathways. It acts as a positive regulator of salt and drought stress and as a negative regulator of cold response.

4.2 Regulation during Biotic Stress and Defense

Plants interact with a huge array of organisms such as viruses, bacteria, fungi, insects, nematodes, and herbivores throughout their lives. Complex and integrated defense signaling pathways that allow these to respond to individual organisms have been evolved in a variety of ways. The disease resistance in plants against pathogens invokes hypersensitive responses. There is an activation of an array of defense genes and the production of antimicrobial phytoalexins. Plants are also able to develop systemic acquired resistance in uninfected portions of plant subsequent to attack by the same or unrelated pathogen.

These responses are initiated by the recognition of pathogen. A plant resistance gene interacts with pathogen avirulence (*avr*) gene and may trigger a hypersensitive response that results in cell death. Recent studies point out that MAPK cascade is the integrative point to downstream responses after perception of different pathogens and elicitors. Fungal elicitor xylanase from *Trichoderma vivde* and bacterial elicitor harpin have been found to induce MAPK-like activities. MAPK such as SIPK (salicylic acid induced protein kinase) and WIPK (wound induced protein kinase) are activated by various biotic and abiotic responses.

Virus resistance is mediated by the synthesis of pathogenesis related proteins (PRPs) and virus-induced gene silencing, which involves the recognition of the dsRNA of the virus, its degradation by a DICER-like complex to small 21 to 25 nt fragments and the methylation of promoters that drive gene expression of these viral genes. Bacterial resistance involves a family of proteins known as the *NBS-LRR* (*nucleotide binding site-leucine rich repeat*) family of receptors. These receptor kinases have specificity for different pathogenic proteins and mediate gene for gene resistance against several pathogens. Fungal resistance may involve expression of chitinases, endoglucanases, while herbivory and insect attack is prevented by release of toxic volatiles such as nitriles, isothiocyanates, epithionitriles, and so on, by the action of myrosinases on glucosinolates. Insect attack is also resisted in some plant legumes such as soybean and cowpea by the expression of protease inhibitors that block insect gut proteases.

Many defense genes are activated by a group of transcription factors belonging to the WRKY family. These genes

recognize W-box elements containing a conserved TGAC motif present in several plant defense genes such as class I chitinases, some PRPs, a glutathione S-transferase, and so on. Defense response is also initiated by activation of genes of the phenylpropanoid pathway that results in production of phytoalexins. In addition, many members of ethylene-response factors (ERF) subfamily of AP2 transcription factors (discussed in ethylene section) are also involved in defense. Several ERF genes are regulated by plant hormones, ethylene, jasmonic acid, and salicylic acid and also by pathogen attack. Pti4, Pti5, Pti6 (Pto interacting kinase), which interact with tomato disease resistance proteins are members of ERF family. AtERF3 and AtERF4 are transcriptional repressors, which are induced by both ethylene and JA. Pti4–6 indirectly regulates SA (salicylic acid) responses through interaction with other TFs. These ERF genes are regulated posttranscriptionally by MAPK mediated phosphorylation. ERFs bind target sequence GCC-box in promoters of many pathogenesis related and hormone-induced genes. The overexpression of many of these ERFs confers increased resistance to pathogens. Oligogalacturonide products produced from wound-induced plant polygalacturonase and chitinase also elicit defense responses against attack from both herbivores and pathogens. Systemin, a wound inducible hormone potentiates oxidative bursts in response to oligogalacturonide products to activate genes near the wound site.

4.3 Regulation by Metabolites

4.3.1 Role of Nitric Oxide in Defense

Recent studies have highlighted the role of NO and its interaction with other hormones in many plant defense responses. NO signaling is mediated by three second messengers, namely, cGMP, cADPribose, and Ca^{++}. NO affects the expression of many genes such as *PHENYLALANINE AMMONIA LYASE* (*PAL*) and *PR1*. NO also plays a role in regulating plant cell death and probably facilitates the cell-to-cell spread of hypersenstive response. However, NO can also protect cells from the reactive oxygen species (ROS) mediated cell damage by inducing expression of catalase, SOD, glutathione S-transferase. It is thus a bifunctional modulator of cell death. NO also plays a role in mediating ABA-induced stomatal guard cell closure.

There is an interrelationship between NO, SA, and jasmonic acid in plant defense. NO induces levels of endogenous SA in tobacco and *Arabidopsis*. NO inhibitors attenuate SA-induced systemic acquired resistance (SAR). On the other hand, NO function requires SA and overexpression of SA-degrading enzyme salicylate hydroxylase abolishes NO-induced resistance against TMV. There is cross talk between NO and JA/wounding signaling pathway during defense. Both wounding and JA induce NO synthesis through an unidentified enzyme. Conversely, NO activates genes that encode JA biosynthetic enzymes. This NO-induced synthesis of JA is observed in SA-deficient plants indicating that SA negatively regulates NO-mediated JA synthesis.

4.3.2 Role of Reactive Oxygen in Stress

Biotic and abiotic stresses lead to production of reactive oxygen intermediates (ROS/ROI). These were first considered to be toxic byproducts of aerobic metabolism but now these are also considered as signaling molecules, which activate various processes such as abiotic stress,

defense against pathogen acclimation, and programmed cell death. These are also involved in stomatal closure. Various types of stresses like salt, chilling, heavy metals, ultraviolet radiation, ozone, mechanical stress, and pathogen attack enhance cellular ROI levels from 240 $\mu Ms^{-1}O_2^-$ to 720 $\mu Ms^{-1}O_2^-$. Since ROI, though toxic, participates in signaling events, plants require two different mechanisms to regulate intracellular ROI concentration; one enables the detoxification of excess ROI and the other enables fine modulation for low levels of ROIs for signaling purposes.

Superoxide dismutase (SOD), ascorbate peroxidase (APX) and catalase (CAT) are major ROI scavengers. SOD and APX pathways are found in almost all the cellular compartments whereas CAT pathway for ROI scavenging is restricted to only peroxisomes. APX has very high affinity for H_2O_2 and is believed to be a fine modulator of ROI for signaling, whereas CAT is thought to be responsible for the removal of excess ROI during stress. Ascorbic acid and glutathione play crucial role in plant defense against oxidative stress. Mutant and transgenic plants with suppressed/altered ascorbic acid and glutathione level are hypersensitive to stress conditions. It is important to maintain a high ratio of reduced:oxidized state of these antioxidants in the cell for proper scavenging of ROI.

Besides scavenging, reduced ROI production can also be helpful in stress conditions. Plants reduce ROI during stress through anatomical and physiological adaptation. ROI production is also decreased by alternative channeling of electrons in organelle electron transport chains by alternative oxidases (AOX). ROIs also play a role in defense of plants against biotic stress that is different from abiotic stress. During pathogen attack, enhanced enzymatic activities of plasma membrane–bound NADPH oxidases, amine oxidases, and cell wall bound peroxidases produce ROI. H_2O_2, produced during the response, activates many plant defense responses along with SA and NO. SA and NO suppress activities of APX and CAT resulting in overaccumulation of ROI and activation of programmed cell death (PCD). The suppression of ROI scavenging mechanisms together with the synthesis of NO is crucial for the activation of PCD. The opposite roles played by ROI during abiotic and biotic stress could be due to the action of SA and NO, from cross talk between different signaling pathways or from differences in the steady state level of ROIs produced during different stresses.

A simplified hypothetical model for ROI mediated–signal transduction pathway involves sensing of H_2O_2 by a sensor followed by activation of calmodulin and an MAP kinase cascade. This in turn activates or deactivates several transcription factors. These factors regulate the response of plants to oxidative stress. Recently, an *Arabidopsis* mutant *radical-induced cell death1* (*rcd1*) has been identified which, upon ozone exposure, exhibits higher ROI production, reduced sensitivity to ABA, ethylene and methyl jasmonate, and has altered expression of several hormone-regulated genes. RCD1 belongs to the WWE protein–protein interaction domain protein family and is suggested to act as an integrative node in hormonal signaling and in regulation of stress responsive genes.

5 Developmental Regulation of Genes

In plants, development of different organs is governed mainly by members of the MADS-box gene family and the

homeodomain family of transcription factors. Different genes responsible for meristem identity and development of specific organs are expressed at specific stages where they activate or repress other genes to bring about development. While the homeodomain genes specify organ identity in roots, stem, and leaves, the MADS-box genes are mainly involved in flower and fruit development. Owing to the complexity of developmental regulation, only the major transcription factor genes involved in each process will be mentioned.

Seed development is governed by the action of *ABI3* and it activates genes for LEA proteins that protect the seed from desiccation effects. Apical basal pattern of the plant is determined by *GNOM* (*GN*), *MONOPTEROS* (*MP*), *GURKE* (*GK*) and *FACKEL* (*FK*), while radial patterning is governed by ARABIDOPSIS THALIANA MERISTEM LAYER1 (*ATML1*) and *KNOLLE*. Endodermal cell identity is governed by *SCARECROW* (*SCR*) and *SHORT ROOTS* (*SHR*), while root meristem is regulated by *HOBBIT (HBT)*. Shoot meristem and shoot development are governed by *SHOOT MERISTEMLESS* (*STM*), *KNOTTED* (*KN*) and *WUSCHEL* (*WUS*), while leaf development is controlled by *AUGUSTFOLIA* (*AN*), *ROTUNDIFOLIA* (*ROT*), *PHAVULOTA* (*PHV*), *PHABULOSA* (*PHB*), and *PHANTASTICA* (*PHAN*), the last of which is a repressor of *KNOX* genes. Trichome development is regulated by *GLABRA1(GL1*) and *TRANSPARENT TESTA GLABRA*(*TTG*). The floral meristem genes *LEAFY* (*LFY*) and its repressor *FLOWERING LOCUS C* (*FLC*) control the transition from vegetative phase to flowering phase. The floral organ identity genes consist of four classes. Their interactions determine the development of the sepals, petals, stamens, and carpels. These include *APETALA1* (*AP1*) and *APETALA2* (*AP2*), which are A class genes, *APETALA3* (*AP3*) and *PISTILLATA* (*PI*), which are B class genes, *AGAMOUS* (*AG*), which is a C class gene and *SEPALLATA 1, 2,* and *3 (SEP1, SEP2, SEP3),* which interact with all the three classes. Genes such as *RIPENING INHIBITOR* (*RIN*) play a role in fruit ripening while *SHATTERPROOF1* and *2* (*SHP1* and *SHP2*), *AGAMOUS LIKE 15* (*AGL15*), and *JOINTLESS* control dehiscence and abscission.

The control of development is brought about by a complex interaction of the different gene products. MADS-box genes are believed to function as homo- and heterodimers through interaction from their K-box, which is unique to plant MADS genes. They recognize a sequence motif $CC(A/T)_6TGG$ also known as the *CArG box*.

6
Epigenetic Regulation of Plant Development

In recent years, studies on epigenetic control of eukaryotic gene expression have added a new dimension to our understanding of gene regulation. It is apparent now that activation and repression of genes by histone modification and chromatin remodeling as well as by small RNA molecules such as miRNAs and siRNAs plays an important role in development and temporal and spatial expression of genes. In plants too, several recent studies have highlighted the role of these processes in gene expression.

6.1
Role of miRNAs in Plant Development

MicroRNAs are small 22 to 25 nt RNAs that regulate gene expression by binding

specific sequences in target genes and suppressing their expression. A study of the plant microRNAs and their putative target sequences showed that in about 70% of the cases the target genes were transcription factors and these are mainly related to plant developmental processes.

Three class-III HDZIP genes *PHABULOSA* (*PHB*), *PHAVULOTA* (*PHV*), and *REVOLUTA* (*REV*) have recently been shown to regulate miRNAs. While *PHB* and *PHV* are involved in determining adaxial and abaxial polarity in lateral organs, *REV* is required for leaf development and vascular patterning. All three genes contain targets for two miRNAs, miR165 and miR166, and regulation probably occurs by RNA degradation.

Some AP2 (*APETALA2*)-like genes have also been shown to be regulated translationally by miR172. It has been shown that AP2 (which is involved in flower development and is transcribed in all four whorls of the flower), restricts the expression of AGAMOUS, a class C gene that is responsible for carpel and stamen identity, to whorls 3 and 4. This is made possible by expression of miR172 in whorls 3 and 4 and its repression of AP2 translation in whorls 3 and 4. This results in accumulation of AGAMOUS in these whorls. miR172 is not expressed in whorls 1 and 2 and thus allows AP2 protein to accumulate in these whorls and repress *AGAMOUS* expression.

6.2 Repression by DNA Methylation

Another mechanism of regulation involves the POLYCOMB group of genes that are involved in methylation of DNA and long-term memory of repression. In plants, the Polycomb group (PcG) of genes are involved in regulation of MADS-box genes and thus control development, floral identity, response to vernalization, flowering and seed development, and so on. Examples include the repression of *AGAMOUS* (responsible for carpel and stamen development) by *CURLY LEAF* and *EMBRYONIC FLOWER* and of *FLOWERING LOCUS C* (a floral transition repressor) by *VERNALIZATION*. In both cases, the target genes are repressed by hypermethylation of an intron.

Other genes related to DNA methylation and chromatin remodeling have been identified in plants and include *DECREASED DNA METHYLATION (DDM1), DNA METHYLTRANSFERASE1* (*MET1*), *CHROMOMETHYLASE 3* (*CMT3* – a DNA methyltransferase), *LIKE HETEROCHROMATIN PROTEIN1* (*LHP1*), *DOMAINS REARRANGED METHYLASE 1* and 2 (*DRM1* and *DRM2*), *KRYPTONITE* (*KYP* – an H3K9 methyltransferase), and *DEMETER* (a DNA glycosylase).

Summary

Plant gene expression presents a complex picture of gene activity when compared to other eukaryotes. The nuclear genome and organelle genome show a lot of difference in their transcription and translation machinery. Several RNA polymerases are encoded, which have specific roles in nuclear and organelle gene transcription. In general, several factors together with RNA polymerase bind to the promoter and other cis-elements of the gene and begin transcription. The mature transcript may be generated by a variety of posttranscriptional processing, which prepares the transcript for translation on ribosomes. The signal for the start of transcription

may be constitutive, developmental or hormonal as a result of various changes sensed by plants in its environment. The signal may include ions, small molecules like hormones and other metabolites, and light and various kinds of stresses to which plants are exposed. Several of these signals are mediated through a signaling system, which includes receptors, transcription factors, and a variety of MAP kinases. Besides transcriptional regulation, genes are also regulated posttranslationally. Selective degradation of activators and repressors of signal pathway by the proteasome is turning out to be a very important means of controlling signal transduction. Changes in chromatin structure histone modification and DNA methylation have also been shown to regulate gene expression in plants.

Keywords

Pathogenicity Factors
Proteins, toxins, exopolysaccharides, and other elicitors used by viruses, bacteria, fungi, and oomycetes to cause disease on plants.

Necrotrophy
Infection where the pathogen causes plant cell death and utilizes the nutrients released.

Biotrophy
Infection where the pathogen taps into living plant cells to obtain its nutrients.

Nonhost Resistance
The general resistance that makes a particular plant species resistant to a potential pathogen.

Host Resistance
The resistance that occurs within a plant species whereby some individuals are resistant while others are susceptible.

Resistance Genes
Genes present in plants that are responsible for triggering host resistance to pathogens.

Systemic Resistance
A form of resistance response that spreads from the initial trigger through the plant via the vascular system.

The interactions between plants and microbes can take many forms and involve complex molecular signaling between different organisms. In some cases, the interactions result in plant disease as the virus, bacterium, fungus, or oomycete pathogen colonizes the host tissue and accesses nutrients for its own development and proliferation. The mechanisms through which this occurs are both elegant and diverse, often involving production of specific pathogenicity factors, such as toxins or cell wall degrading enzymes, and suppression of the plant defense responses. In other cases, these plant defenses, which also include complex molecular signaling pathways within the plant and may involve structural barriers, nonhost resistance, induced resistance, and systemic resistance, are successful and combat the potential pathogen.

1 Introduction

The interactions between plants and microbes involve complex molecular signaling between different organisms and can have a range of outcomes. Many microbes exist as saprophytes living off nutrients released from plants, but some have developed specific mechanisms and strategies to manipulate plant metabolism and basal defenses for their own growth and development. It is these specialist organisms, and, in particular, those that infringe on our food supply and environment, that form the basis for studies in plant pathology.

The most significant causes of plant disease are viruses, bacteria, fungi, and oomycetes, and there are numerous historical examples where these have had a major impact on human populations and health through crop failures, starvation, and toxicity. The potato blight oomycete *Phytophthora infestans*, for example, resulted in complete failure of the potato crop in Ireland in 1846, contributing directly to 1 million deaths, while an epidemic of Southern corn leaf blight, *Bipolaris maydis*, resulted in a 50% corn yield reduction in the United States in 1970 at an estimated cost of $1 billion. Today, plant diseases are estimated to be responsible for a reduction in potential crop yields of around 10 to 15% annually worldwide. Furthermore, new diseases continue to emerge as pathogens evolve to overcome current control measures, or through the movement of plants and plant products between countries as part of global trade.

While there are a diverse range of strategies used by pathogens for infection and by plants for defense, by concentrating resources on model plant systems such as *Arabidopsis thaliana*, rice, and maize, and the pathogens that infect these plants, there has been a rapid increase in our understanding of molecular plant pathology. There are increasing numbers of genome sequences and tools for mining this information. The capacity to generate large numbers of mutagenized plants combined with elegant screens to select mutant phenotypes allows specific pathways to be targeted, while transformation systems and targeted gene silencing allow sequences to be connected to function through reverse genetics approaches. Gene expression profiling, proteomics, and metabolomics are being used extensively, and much of this information is readily available through bioinformatics resources. In this chapter, we will review the molecular mechanisms used by pathogens to cause disease on plants along with the methods used by plants to defend themselves against these pathogens.

2 How do Pathogens Cause Disease?

2.1 Viruses

2.1.1 General Properties of Plant Viruses

Viruses are common in plants and have been organized into 73 genera on the basis of size, shape, nucleic acid composition, sequence comparisons, transmission characteristics, and host range. The majority (90%) of plant viruses possess single-strand RNA genomes in the plus (+) or sense polarity. There are, however, some significant plant viruses with genomes of dsRNA (the phytoreoviruses), ssDNA (the geminiviruses), and dsDNA (the caulimoviruses). In most cases, the viral genome is a single segment of nucleic acid encapsidated in a simple protein coat, and 50% of plant viruses are rod

shaped (flexuous or rigid), while most of the rest are isometric. There are, however, some viruses that have segmented genomes and in many cases the segments are encapsidated in different particles resulting in multicomponent viruses, where all the components must be present in the plant cell simultaneously for it to replicate and spread.

Many plant virus genomes have been sequenced and they are generally very compact, with the genes separated by very short intergenic regions or overlapping. Normally, they encode only a small number of polypeptides, relying on host cell components for aspects of their translation, replication, and movement. Some of the encoded polypeptides are multifunctional, and, in general, the basic requirements for a successful virus are a replicase to promote replication of the genome, a coat protein to encapsidate this genome, a movement protein to enable the virus to move between cells, and a vector transmission protein to allow transmission between plants. The basic infection strategy for a model plant virus is shown in Fig. 1.

2.1.2 Virus Replication and Assembly

The majority of plant viruses with ssRNA genomes replicate in the cytoplasm of plant cells, often associated with membrane-bound cytoplasmic inclusions (viroplasms) containing host endoplasmic reticulum. A number of replication strategies have been developed by viruses to ensure that all the functions encoded by their genomes are translated. The first of these is the production of subgenomic RNAs (see Fig. 1). In this process, the capped viral genome is recognized by the host translation machinery as mRNA, and the 5′-most cistron up to the first stop codon is translated. In these viruses, this cistron is invariably the replicase, which has three functional components, an RNA-dependent RNA polymerase (RdRp), a helicase, and a methyltransferase. The helicase and RdRp, possibly in conjunction with host factors, act on the (+)-strand RNA template to produce a complementary (−) strand, and then use signals within this strand to produce more full-length (+) strands and subgenomic (+) strands for each of the downstream genes. These subgenomics are capped by the methyltransferase and in turn translated to produce the separate functional proteins such as the movement and coat proteins.

An alternative approach used by some (+)-strand viruses such as *Cucumber mosaic virus* is to effectively package each of the subgenomic RNAs into separate particles resulting in multicomponent viruses, while a third strategy exemplified by the *Potyviridae* is to have no stop codons in the genomic RNA and produce a single large polyprotein. This is then cleaved post-translationally into the different functional polypeptides, triggered by virally encoded proteinases within the polyprotein. For double-strand and negative-strand RNA viruses, similar translation mechanisms occur, but the initial replication process is promoted through the packaging of 10 to 20 copies of the replicase protein into the viral particles.

The ssDNA geminiviruses have a different problem to overcome for replication. Replication occurs in the nucleus of the infected plant by recruiting plant enzymes for conversion of the circular ssDNA genome into dsDNA, which is then transcribed to produce the viral replicase, and replicated by a rolling-circle mechanism. However, for this to happen, the virus has to induce a permissive state for DNA replication in already differentiated plant cells, and it appears to do this through

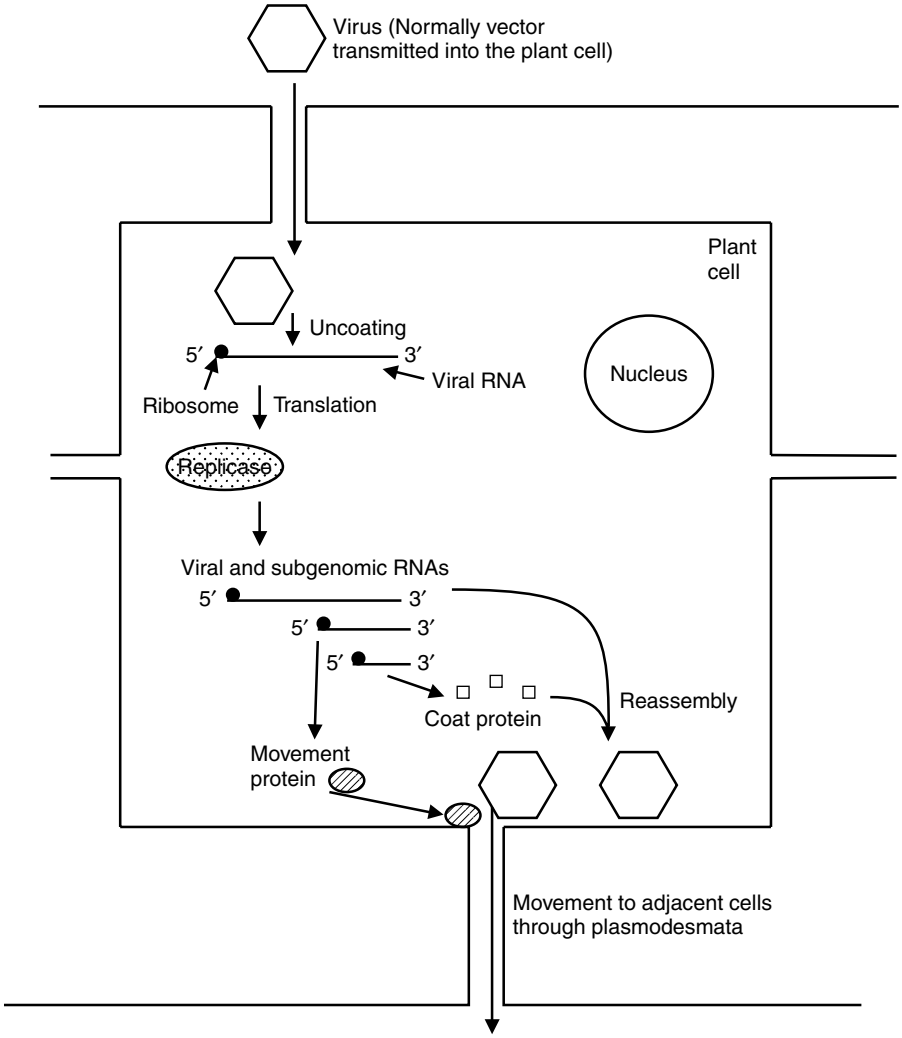

Fig. 1 General scheme for virus spread within plants. The virus enters the plant cell through wounds made mechanically or by a vector. The RNA then becomes uncoated and, at the same time, is surrounded by ribosomes for protection. Following replication and production of more coat protein, the virus reassembles or forms a ribonucleoprotein complex and is then moved between adjacent cells through the plasmodesmata, facilitated by the virally encoded movement protein.

association of the replicase with a plant retinoblastoma–related protein, which effectively regulates the cell cycle and shifts mature plant cells into the S-phase.

The dsDNA *Caulimoviridae* are plant retroviruses that replicate via reverse transcription, and use a ribosome-shunting mechanism to ensure that all the open reading frames on the polycistronic 35S transcript are translated. This 35S RNA is a full-length transcript, and is then copied by the virally encoded reverse

transcriptase into the DNA viral genome, although unlike retroviruses of vertebrates and bacteria, this does not appear to involve integration into the plant genome.

Assembly of plant viruses within cells following replication and translation is a process that has been best studied for *Tobacco mosaic virus* (TMV). This rod-shaped virus has a 6400-nucleotide ssRNA genome encapsidated in 2130 copies of a single 17.6-kDa coat protein subunit. These subunits reassemble spontaneously into discs containing 34 units in 2 rings of 17, and in the presence of the viral RNA, these rings dislocate to form a helix of 16.33 subunits/turn. The viral RNA possesses a specific protein-binding motif, which binds into a groove within the helix, and additional disks are then recruited and dislocated as the remainder of the RNA is wound up inside the extending helix until the entire genome has been encapsidated. Isometric virus particles appear to follow similar spontaneous reassembly processes, with the subunits taking up a basic 60T structure, where T is an integer.

2.1.3 Viral Movement Within Plants and Transmission between Plants

To spread within plants, viruses must move from the initial infection site systemically to other parts of the plant. The majority of viruses are initially introduced into epidermal or mesophyll cells by insect vectors and must then spread through the leaf tissue from cell to cell and then into the phloem. This short-distance movement between cells occurs through symplastic connections known as *plasmodesmata*. However, the normal size exclusion of plasmodesmata only allows solutes of less than 1.5-nm radius to pass, which is too narrow for the passage of intact virions. Viruses therefore encode movement proteins, which widen these channels to allow either intact particles or ribonucleoprotein complexes to pass through. The main features of these movement proteins are that they are nonstructural nucleic acid binding proteins that are often not virus-specific and can facilitate the movement of unrelated viruses. They appear to work by one of two mechanisms. One group, typified by the TMV 30-kDa protein, act as chaperones, binding to the viral RNA, and guiding it first toward the plasmodesmata, and then through them in a process controlled by phosphorylation mechanisms. The second group appears to form a tubule structure through the plasmodesmata and then forces the 40- to 80-nm diameter intact virions through these by a ''treadmilling'' mechanism. Once the viruses or ribonucleoproteins have passed through the plasmodesmata, the movement proteins return these channels to their normal size exclusion to prevent leakage of other solutes. Eventually, cell-to-cell movement results in the viruses or ribonucleoproteins entering the vascular system, and, once there, they move from source to sink tissues along with photoassimilates. They can also be unloaded back into nonvascular tissue, essentially by the same short-distance movement mechanisms.

To move between plants, most viruses recruit vectors and, in particular, arthropods such as aphids, whiteflies, and hoppers. The relationship between the virus and its vector is generally a specific one, and the amount of genetic variation that can be tolerated in a viral genome is often determined by the need to maintain this specific virus/vector relationship. Traditionally, viruses have been categorized as nonpersistent, where the virus associates with the mouthparts of the insect rapidly, but is lost equally rapidly when the insect

feeds again, and persistent, where the virus is taken up into the gut and hemolymph during feeding and then enters the salivary glands of the insect and so is transmitted every time the insect feeds subsequently. Persistent viruses in turn are subdivided into propagative, which can replicate in the insect as well as the plant, and circulative, which only replicate in plants.

Many viruses, whether transmitted by insects, nematodes, or other vectors encode polypeptides and/or polypeptide domains within their coat proteins that are essential for the transmission. These domains encompass specific motifs that are required for protein-protein interactions and ensure that the virus binds to specific proteins within the insect. There are also a significant number of viruses (around 20%) that are transmitted through seed rather than by vectors, either moving into the gametes prior to fertilization, or directly infecting the embryo after fertilization. This capacity for seed transmission is also controlled by genes within the virus and the host.

2.1.4 **Affects of Virus Infection on Plant Processes**

Viral infections cause major alterations to host gene expression and metabolic processes. These include accumulation of starch and soluble sugars, increased respiration, decreased photosynthesis, an increase in the levels of amino and organic acids in infected areas, and alterations to plant defense responses. As a viral infection front passes through a plant, it induces a permissive state in cells for its own replication, and the host cells then return to near normality once the front has passed. This permissive state involves host gene ''shutoff'' in which the majority of genes are temporarily downregulated, except for those that are important for the virus, levels of which remain the same or increase. For example, expression of genes for actin and beta-tubulin, important for cell-to-cell movement of the virus, may remain unchanged, while heat-shock protein gene expression increases, which may be important for ensuring that the changes in gene expression are only transient, and that the host cell does not die.

Although host gene expression effectively returns to normal once the infection front has passed, it is clear that changes do occur to some metabolic processes, as indicated by the changes to respiration, starch accumulation, and so on, and these changes result in the characteristic viral symptoms of patches of chlorosis, often in the form of mosaics. It has been postulated that plant signal molecules such as salicylic acid and soluble sugars may be responsible for these physiological changes.

A further property of plant viruses that has recently been identified is their ability to interfere with plant defense mechanisms. Plants have a specific defense mechanism, posttranscriptional gene silencing (PTGS), which is targeted against foreign RNA such as viral genomes in the cell cytoplasm. This mechanism, like RNAi in animals, involves recognition of dsRNA, (for example, viral replicative forms), and degradation of this RNA by Dicer RNase III-type enzymes. In plants, the resultant small interfering ribonucleoprotein (siRNP) complexes also enter the vascular system and appear to enter a race with the virus, such that if the virus moves faster systemic infection occurs, while if the silencing mechanism catches the virus, infection is aborted. What has now been shown is that some viruses encode within their genomes specific proteins, such as the *Potato virus Y* (PVY) HC-Pro, that are able to block both the initiation and

maintenance of PTGS in a counterdefense strategy.

2.2 Bacteria

2.2.1 General Properties of Plant-Pathogenic Bacteria

Most plant-pathogenic bacteria are rod-shaped and Gram negative and possess flagella, and the best studied at the molecular level are species of *Pseudomonas*, *Xanthomonas*, *Erwinia*, *Pantoea*, *Ralstonia*, and *Agrobacterium*. Prior to colonization, bacteria that are potential pathogens may inhabit the leaf surface or colonize the soil surrounding roots at low density. For pathogenicity to occur, specific pathogenicity factors, often encoded in pathogenicity islands (PAIs) within the bacterial nucleic acids, are required. These factors may be exopolysaccharides, toxins, cell wall degrading enzymes (CWDEs), plant hormones, or other effector proteins, which enable the bacterium to access nutrients for its own growth, while at the same time suppressing or evading the plant defense mechanisms. Furthermore, these factors are often delivered into the host cell cytosol by specific secretion mechanisms, and the whole process is initiated through complex molecular signaling within bacterial populations, and between bacteria and plants.

2.2.2 Establishing Infection

A common mechanism used by bacteria that has been shown to be important for initial plant colonization is quorum sensing. This is a communication mechanism used by bacteria that enables them to sense population density and respond through the regulation of expression of specific genes. In Gram-negative systems, the bacteria produce autoinducers, through the LuxI family of acyl-homoserine lactone (AHL) synthases, which are diffusible signal molecules that can pass in and out of bacterial membranes. At high cell density, these autoinducers reach a threshold level in the external environment that is detected by *LuxR*-encoded transcriptional activators present in the bacterial membranes, which regulate transcription of target genes.

In many cases, further regulatory complexities involving chemical signals emanating from plants have been added to the basic LuxI/LuxR system, such as in the regulation of CWDE and exopolysaccharide (EPS) production of *Erwinia* spp., *Pantoea* spp. and *Ralstonia solanacearum*, and in the conjugal transfer of the Ti (tumor inducing) plasmid in *Agrobacterium tumefaciens*. In *R. solanacearum,* for example, swimming motility mediated by flagella is regulated through PhcA, a Lys-R type global regulator, expression of which is in turn controlled by a quorum sensing mechanism. At low bacterial cell density, as occurs in the rhizosphere, PhcA is not expressed so that the motility and *CWDE* genes are switched on. As bacterial population density increases, for example, through colonization of the xylem, PhcA is expressed, the motility and *CWDE* genes are downregulated, and production of the EPS pathogenicity factors is upregulated.

2.2.3 Pathogenicity Factors

Bacteria utilize a wide range of pathogenicity factors and effector molecules to colonize plants, and different secretion mechanisms are used to deliver these into the plant cytosol. Necrotrophic bacteria, such as the soft rots *Erwinia carotovora* and *Erwinia chrysanthemi* secrete cocktails of CWDEs, including pectinases,

cellulases, and proteinases to soften and macerate the plant tissue and release nutrients. The proteinases, which contain C-terminal secretion signals, are secreted by a type I secretion mechanism driven by ATP hydrolysis, while the pectinases and cellulases are secreted by the type II Out secretion mechanism. Regulation of *CWDE* gene expression is complex and involves plant cell wall breakdown products as well as other plant factors, and environmental factors such as temperature, osmolarity, and nitrogen starvation.

Bacterial toxins, which generally induce chlorosis in plants and increase the severity of many diseases, are important pathogenicity factors, particularly of many *Pseudomonas syringae* pathovars. Coronatine, for example, which has structural similarities to methyl jasmonates (a signaling molecule in higher plants), causes cell wall thickening and changes in chloroplast structure, and its production is regulated through a two-component histidine kinase regulatory system in response to temperature changes. Phaseolotoxin, produced by halo blight of beans, is also temperature regulated and inhibits the enzyme ornithine carbomyltransferase (OCTase) in plants, resulting in arginine deficiency and ornithine accumulation. The bacterium itself copes with this toxin by producing an isozyme of OCTase that resists the toxin.

While these toxins are important for increasing the severity of many pseudomonas diseases, they are not essential and are only part of a complex of effector molecules that these and other plant pathogenic bacteria use to cause disease. Many of these effectors appear to be delivered into plants by a type III secretion mechanism, in which a structure is produced that spans the bacterial membranes and forms an external hrp-pili appendage that acts as a needle through which the effectors are translocated (Fig. 2). These secretion systems are encoded by clusters of genes referred to as *hrp* (hypersensitive response and pathogenicity) genes analogous to the virulence associated type III secretion genes of animal pathogenic bacteria such as *Yersinia* spp. Expression of the *hrp* genes is regulated by environmental and host plant factors, and it has been shown that they are not induced in rich artificial media, but are in minimal media that mimics the content of plant apoplastic fluids. In *R. solanacearum*, for example, the key regulatory protein PrhA is induced by plant cell wall factors, though, interestingly, this occurs with both host and nonhost cell wall extracts, suggesting that the host range of the bacterium is determined by the factors that are secreted and not by the ability to form a secretion mechanism. In *Erwinia* spp. and *Pseudomonas* spp., regulation of *hrp* genes is by a different mechanism involving responses to low levels of carbon and nitrogen, low pH, and low temperature.

The effector molecules secreted by type III systems are diverse in structure and function. Some of these were initially characterized as avirulence proteins because they were identified as components of gene-for-gene resistance (Sect. 3.4). However, it is now apparent that their main role may be to suppress plant defense responses to ensure survival of the colonizing bacteria, and their classification as avirulence peptides is a consequence of the ability of plant defense surveillance mechanisms to detect them. For example, AvrPtoB from *P. syringae* has been shown to act as a general inhibitor of programmed cell death, while others have nuclear localization signals and are suggested to regulate host gene expression.

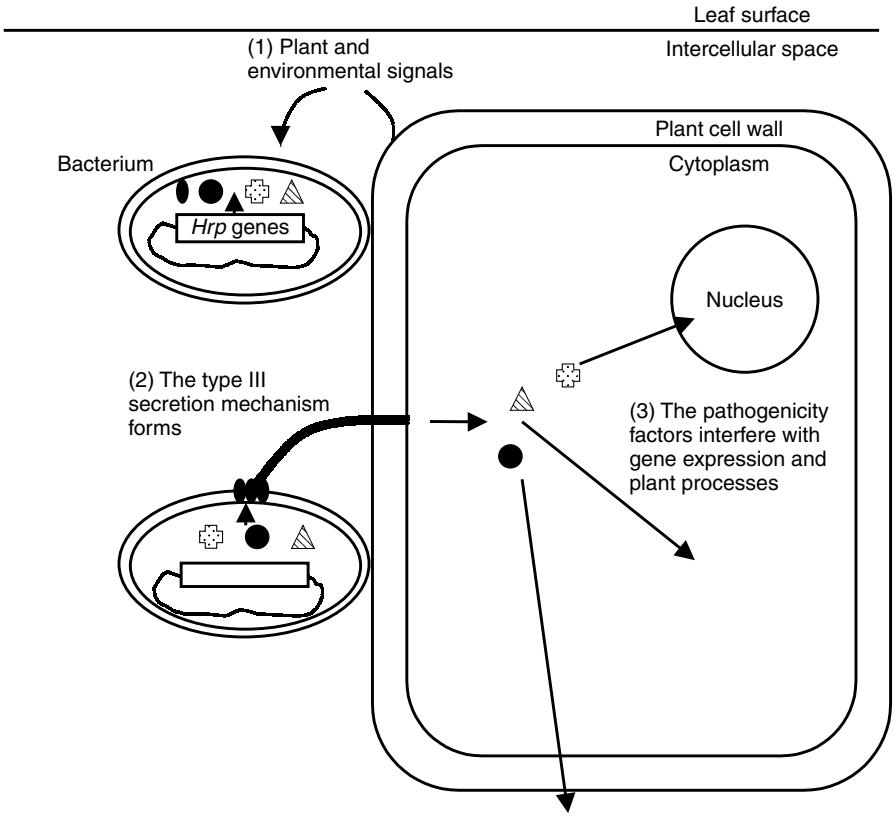

Fig. 2 Model for the infection process of a bacterial plant pathogen. Plant and environmental signals regulate the *hrp* genes (1) resulting in the formation of the type III secretion mechanism and hrp pilus (2) through which pathogenicity factors are secreted that interfere with plant processes, (3) facilitating bacterial multiplication and disease.

The role of many of the other effectors secreted by type III systems has yet to be established.

In some species of *P. syringae*, such as *P. syringae* pv. *savastanoi*, the hrp system is involved in the secretion of enzymes involved in the biosynthesis of auxins. The resultant auxin production in infected plants then proceeds in an uncontrolled way, since this biosynthetic pathway is different to the one normally used by plants for auxin production, and results in gall formation. Equivalent auxin biosynthetic genes and gall production are also a feature of the crown gall bacterium *Agrobacterium tumefaciens*. However, in this bacterium, the genes are carried on a 180-kb pathogenicity island referred to as the Ti (tumor-inducing) plasmid, and it is the genes themselves that are secreted into the plant by a type IV secretion mechanism. This type IV secretion is encoded by a set of genes on the Ti plasmid called the *vir* genes, and the expression of these is regulated by chemical signals emanating from wounded plants such as lignin and flavonoid precursors. These wound signals are detected and transmitted via

a two-component histidine kinase regulatory system (VirA and VirG) to switch on the other *vir* genes. These gene products, in turn, excise a fragment of DNA (the T-DNA) encoding the auxin biosynthetic genes and opine biosynthetic genes from the Ti plasmid, and this DNA is then enveloped in other Vir proteins and secreted out of the bacterium through the T-transporter (assembled from further Vir proteins), which is a pilus that acts as a conduit into the host cytoplasm. The T-complex then targets and enters the plant nucleus, and the T-DNA integrates into the genomic DNA facilitated by plant proteins. The auxin and opine biosynthetic genes are then expressed, resulting in the gall formation and biosynthesis of opines, which are modified amino acids that the bacterium uses as a source of nutrients as it proliferates in the gall.

A final class of virulence factors used by some bacteria such as *R. solanacearum, Xanthomonas campestris, Pantoea stewartii,* and *Erwinia amylovora* is the production of exopolysaccharides (EPS). Gene expression for the biosynthesis of these is upregulated in response to quorum sensing (see Sect. 2.2.2) and the resultant sugar polymers appear to have a double role in pathogenicity. Firstly, they produce a fluidal slime barrier around the bacterium to protect it against desiccation on leaf surfaces and so on, and, secondly, they provide a defense against toxic plant compounds and plant defenses. The regulation of these to ensure that they are only produced when the bacteria reaches a high cell density may be a mechanism to ensure that plant defenses are not activated too early in invasion, so that the bacteria have time to prepare themselves for a ''mob'' attack.

2.3 Fungi and Oomycetes

2.3.1 General Properties

Fungi form the most extensive group of plant pathogens, and of the more than 74 000 known species, more than 10 000 can parasitize living plants to varying degrees. In addition to the true fungi (which characteristically produce mycelia containing glucans and chitin), a number of organisms that were once classified as fungi, but do not contain chitin, also cause plant disease. These are the oomycetes, which are now classified in the Chromista kingdom, and contain such notorious pathogens as *Phytophthora infestans* (potato blight), the white rusts, the water moulds, and the downy mildews. However, both oomycetes and true fungi have similar mechanisms of pathogenicity and infection strategies in that they are dispersed as spores, which may be carried long distances by wind and air currents or may be deposited in the soil and/or splash dispersed, so they will be considered together in this section.

To colonize plants, fungi and oomycetes adopt a range of infection strategies. Some, such as certain blights, are necrotrophic and use CWDEs and toxins to break down plant cells to release nutrients for their own growth. Others, such as the rusts and mildews, are obligate biotrophs in that they can only grow on living plant cells, and tap into these to obtain their nutrients. Others, often referred to as *hemibiotrophs*, use a combination of these approaches, with an initial biotrophic phase as they establish infection becoming necrotrophic as the infection progresses. A further group of fungi, such as ergot, cause limited damage to plants, but are classified as plant pathogens because they produce

mycotoxins that can be harmful to human and animal health.

2.3.2 Establishing Infection

Once dispersed, the spores of a fungus or oomycete must eventually find a suitable host plant, germinate, and penetrate to access the nutrients. Spores of fungi that are dispersed in the air are produced in vast quantities so that by chance some of them will be deposited on suitable host plants. In the presence of moisture, a key requirement for all spore germination and penetration, adhesive pads are formed on the leaf surface containing adhesins and adhesive materials released from the leaf through esterase and cutinase action, which may also act as the chemical triggers of germination. Spores of fungi that are soilborne may remain dormant in the soil for many years until they detect specific chemical signals and/or electrical currents generated around plant roots. In the case of many oomycetes, these signals result in germination of the dormant zoospores, which produce flagella and swim through moisture in the soil toward the source of the signal.

Once the spore has adhered and germinated, it must grow into the plant. In many cases, this involves differentiation of the germ tube to form a specific swelling known as the *appressorium*, and, depending on the fungal species, this may result in direct penetration through the plant cuticle, or through natural openings such as stomata, or wounds, which the germ tube may grow toward directionally in response to chemical and/or physical cues on the leaf surface. One of the best-studied model systems for the mechanisms of direct penetration is the ascomycete *Magnaporthe grisea* that causes the rice blast disease. Here it has been shown that transmembrane integrin proteins sense the leaf surface topography and hardness and transmit this signal through the cell wall, where this and other environmental cues result in changes to the heterotrimeric G proteins inside the cell. These are important intermediates in a number of signaling pathways involving Ca^{2+}-dependent protein kinases, cAMP and protein kinase A, and mitogen-activated protein kinases (MAPK). These result in changes to gene expression such that the tip of the germ tube stops elongating and forms the appressorium, which becomes separated from the germ tube by a septum. Hydrophobins accumulate and self-assemble in this appressorium wall, which then becomes melanized, apart from a small zone in contact with the leaf surface, which forms the appressorial pore. Trehalose is broken down within the fungus along with glycogen granules and lipid bodies, resulting in accumulation of glycerol to concentrations of up to 3.2 M. Moisture surrounding the germinated spore passes through the appressorial wall as these osmotically active solutes accumulate and turgor pressure builds up, which is translated into a mechanical force that pushes the penetration peg out through the appressorial pore and through the plant cuticle. While this physical force may be enough to penetrate the cuticle for some fungi, in other cases not enough force is generated and CDWE are also produced to soften the plant tissue and aid the penetration. These include pectinases, cutinases, and cellulases, and most fungi have multigene families encoding these enzymes.

Having breached the outer defenses, the fungus may then need to overcome further plant defenses to establish infection. These will include preformed antimicrobial compounds (phytoanticipins) and

induced compounds (phytoalexins) (see Sect. 3.2). Some fungi, such as species of *Colletotrichum* and *Botrytis* enter a period of quiescence and wait until the levels of these compounds decline during fruit ripening before they become aggressive. Others such as *Gaeumannomyces graminis* (take-all of cereals) encode enzymes (avenacinase) that detoxify the phytoanticipins (avenacin) or phytoalexins that are produced, and it has also been suggested that the breakdown products of these may in some cases induce a signal transduction mechanism in the host plant that results in suppression of plant defense responses. A further strategy used by *M. grisea* and some other fungi is to use ATP-binding cassette (ABC) transporters to export the antimicrobial compounds out of the fungus, while others secrete compounds (oxalic acid from *Sclerotinium sclerotiorum* or mannitol from *Alternaria alternata*) to suppress active oxygen species-mediated defenses.

2.3.3 Pathogenicity Factors of Necrotrophs

Once established in a plant, a necrotroph aims to kill the host plant cells and utilize the nutrients released. Usually, the resultant macroscopic symptoms of this are brown necrotic areas of dead cells in and around the site of infection. The main weapons used by these fungi are CDWEs, as discussed previously, and toxins. There may also be a role for a group of proteins referred to as the *NLP family* (Nep1-like protein) that have been identified in the range of fungi such as *Fusarium oxysporum*, oomycetes such as *Phytophthora* and *Pythia* species, and some necrosis-inducing bacteria. These proteins appear to induce a programmed cell death in plants by triggering defense responses, although the advantages of this to fungal pathogenicity are uncertain.

Fungal toxins can be divided into three groups, the host-selective toxins, produced mainly by *Alternaria* and *Cochliobolus* species, which are only toxic to the hosts for these fungi, the nonselective toxins that can cause damage to a wider range of plant species, and the mycotoxins, which cause no damage to the plants, but can be fatal to the animals and humans that consume them. The host-selective toxins, such as T-toxin and Victorin of *Cochliobolus* spp. and AAL of *Alternaria alternata* have a broad range of chemical properties (T-toxin is a polyketol, Victorin a chlorinated peptide, and AAL a sphinganine-related compound), and act by affecting mitochondria or host plasma membranes to cause leakage of electrolytes and other small molecules to disrupt photophosphorylation and ATP synthesis, resulting in plant cell death. An interesting feature of these toxins is that their biosynthetic genes tend to be clustered into pathogenicity islands in isolates that produce the toxins, and are completely absent in non–toxin-producing isolates, suggestive of acquisition by horizontal gene transfer. Host nonselective toxins generally have less severe affects on plants, causing chlorotic lesions and wilt, often through the induction of reactive oxygen species in the plant that cause membrane breakdown and nutrient leakage. The mycotoxins by contrast have no obvious affects on plants, but the ergot alkaloids, aflatoxins, trichothecines, and fumonisins that fit into this definition are amongst the most potent toxins known in animals, causing gangrene and convulsions (ergotism) and liver damage and cancers (aflatoxins). Interestingly, the biosynthetic genes for production of these toxins are also generally in pathogenicity islands, although the benefit to the fungus in maintaining these gene clusters is not obvious.

2.3.4 **Pathogenicity of Biotrophs**

Obligate biotrophic fungi such as the rusts, powdery mildews, and downy mildews use stealth to obtain their nutrients from plants. The concentrations of sugars and amino acids in the apoplast of plants are low and not conducive to rapid fungal growth, so most of these organisms form specialized feeding structures known as *haustoria* to invaginate into nutrient-rich plant cells (Fig. 3). Interestingly, convergent evolution has meant that basidiomycete fungi (rusts), ascomycete fungi (powdery mildews), and oomycetes (downy mildews) have all developed this same strategy for acquisition of their nutrients.

Haustoria form by puncturing the plant cell wall, but not the plasma membrane, which remains intact and surrounds the haustoria to form the extrahaustorial membrane. How this occurs without the plant defense responses being triggered is unclear, but analysis of gene expression within haustoria suggests that suppressors, such as bax inhibitors of cell

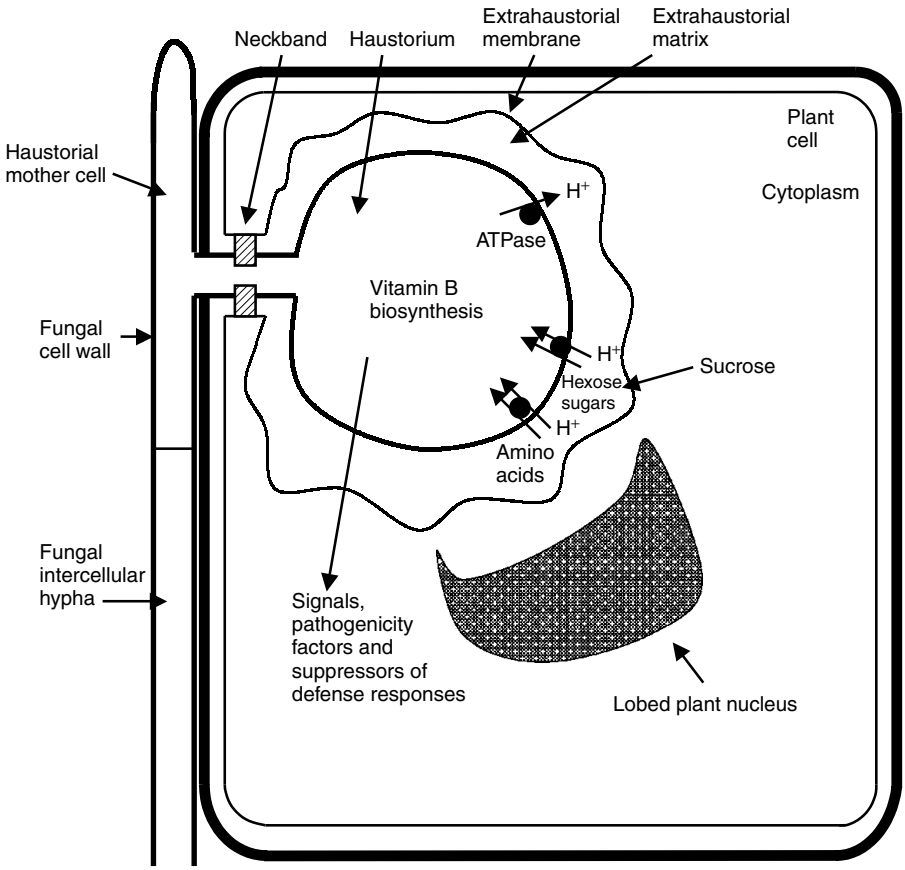

Fig. 3 General properties of a stylized haustorium. The haustorium forms as an invagination into the plant cell and absorbs nutrients (e.g. hexoses and amino acids from the extrahaustorial matrix via proton-symport transporters. Vitamin B biosynthesis also occurs, and signals, pathogenicity factors, and suppressors of defense responses are secreted into the plant cell.

death may be produced by the fungus and secreted along with other signals. Other mechanisms for evading defense responses have also been identified, such as alterations to the cell wall composition of infection structures so that they are not recognized by the plant, controlling levels of proline in plant cells to reduce stress responses, or disrupting plant cell wall/plasma membrane connections (Hechtian strands) so that cell wall associated defense responses are not activated.

For nutrient acquisition, it has been shown that plasma membrane H^+-ATPases, hexose transporters, and amino acid transporters are highly expressed in haustoria and are involved in nutrient transfer into the fungus involving a proton-symport mechanism. To access sucrose from plant cells, for example, it appears that the fungus may secrete an invertase to convert the sucrose to glucose and fructose, which are then taken up by the hexose transporters. Gene expression for thiamine (vitamin B1) biosynthesis, an essential cofactor for several enzymes in carbon metabolism, is also upregulated in haustoria.

A further role for the signals produced by haustoria appears to be to delay senescence in plant cells surrounding the haustoria, resulting in ''green islands'' around infection sites. It has been suggested that the levels of plant hormones and polyamines are being deliberately manipulated in these cells by the fungus to keep them alive and photosynthetically active. The roles of many other effector molecules secreted into plants by fungi and oomycetes have yet to be established, and, as with bacterial effectors (see Sect. 2.3.2), some of these are being identified indirectly as avirulence gene products. In the fungus *Cladosporium fulvum*, for example, a number of avirulence peptides have been identified and are generally small cysteine rich peptides. Of these, it has been proposed that Avr9 may have a housekeeping role in nitrogen metabolism, while Avr4 has chitin-binding properties. In *Rhynchosporium secalis*, the Nip1 avirulence protein is a host nonselective toxin, and mutants have significantly reduced virulence. Over the next few years, as the genomes of more of these biotrophic organisms are sequenced, it is likely that the roles of many more of these effectors in nutrient acquisition and suppression of defense responses will be established.

3 Plant Defense against Disease

3.1 General Properties

Having discussed the strategies used by pathogens to cause disease, we should now consider how plants defend themselves. There are multiple layers to these defenses, as outlined in Fig. 4, and they can be broadly divided into constitutive and induced mechanisms. In many plant species, a combination of these mechanisms will ensure that the particular species is not infected by a particular pathogen (nonhost resistance). For example, the potato blight oomycete is unable to infect wheat. In other cases, the mechanisms may result in particular genotypes within a plant species being resistant, while others are susceptible (host resistance).

3.2 Constitutive Defenses

The first barrier that defends plants against microbes is the wax layer present on the cuticle. This forms a water-repellent

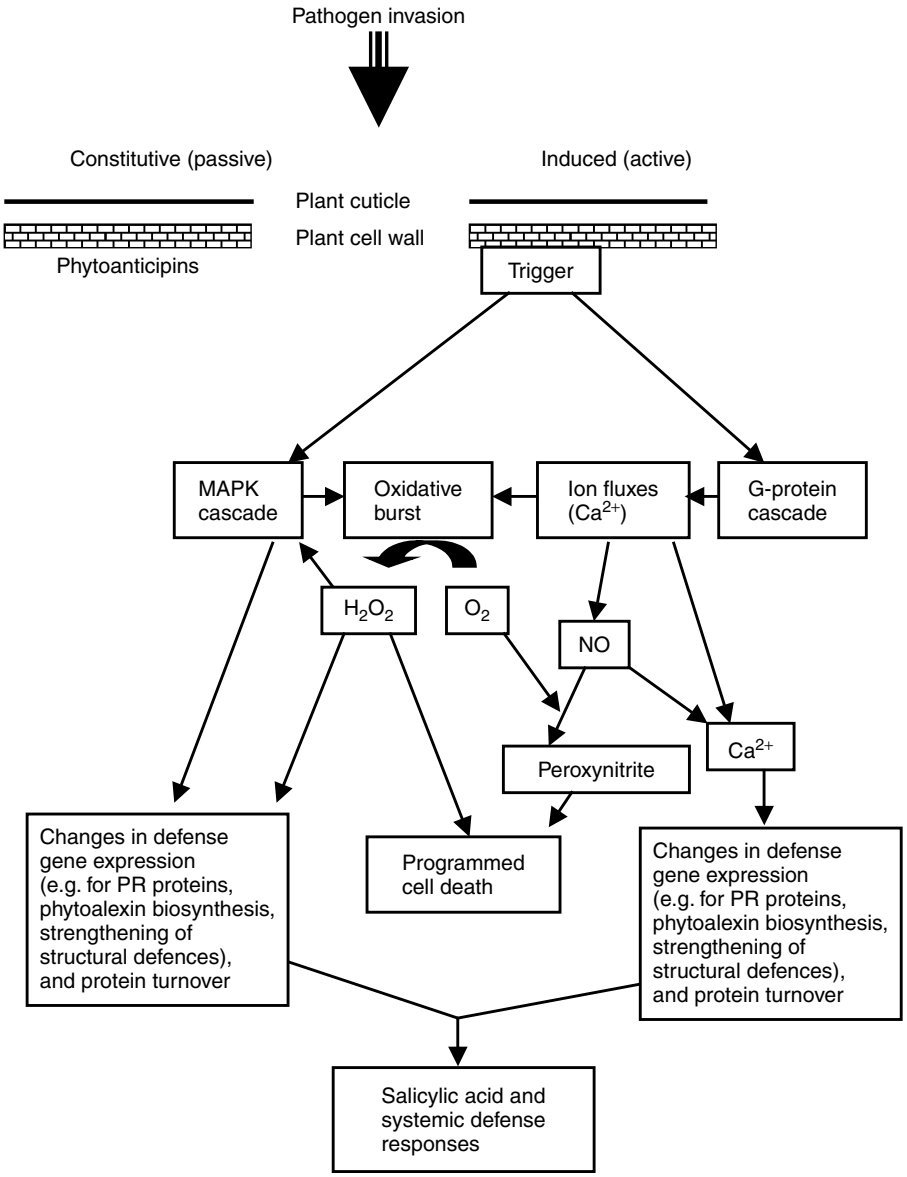

Fig. 4 The multiple layers to plant defenses and signaling. Constitutive defenses are indicated on the left-hand side of the diagram, while induced defenses are shown down the right. The scheme also indicates the interplay between different signaling pathways (see text for details).

surface that prevents the formation of water droplets necessary for bacterial ingress and fungal spore germination. In addition, the epidermal cell walls form an impenetrable barrier to all but those fungi that have the necessary mechanisms for direct penetration (see Sect. 2.3.2). This leaves wounds and natural openings, such

as stomata, as the main weaknesses in structural defenses.

Should a pathogen breach these defenses, antimicrobial chemicals within the plant form a second line of defense. Low molecular weight secondary metabolites such as terpenoid derivatives, saponins, aliphatic acid derivatives, phenolics, phenylpropanoids, alkaloids, and sulfur-containing compounds sequestered in plant cells have been shown to be antimicrobial, either as preformed substances (phytoanticipins) or when their biosynthetic pathways are induced as part of induced resistance (phytoalexins).

3.3 Induced Mechanisms

Induced resistance involves the plant recognizing that it is being invaded and mounting a defense through a triggering of changes in gene expression and production of antimicrobial compounds (Fig. 4). This response is often referred to as the *hypersensitive response* (HR) and involves kinase signaling cascades, ion fluxes, the oxidative burst, nitric oxide (NO), programmed cell death, induction of genes for the biosynthesis of phytoalexins, genes for the strengthening of structural defenses such as peroxidases and lignin biosynthetic enzymes, and production of various novel proteins known collectively as the *pathogenesis-related* (PR) *proteins*. These PR proteins have been grouped into at least 14 classes, and while the biochemical roles of some are not clear, others such as chitinases (PR-3, PR-4, PR-8, PR-11), glucanases (PR-2), proteinases (PR-7), and RNAses (PR-10), are presumed to have roles as hydrolytic enzymes against the invading pathogen, while the defensins (PR-12) and thionins (PR-13) are classified because of their similarities to these antimicrobial compounds found in insects and mammals. The induction of this same battery of defenses appears to occur whether the invading pathogen is a virus, bacterium, fungus or oomycete, and the macroscopic symptoms are small necrotic lesions on the plant. The overall strategy appears to be to combat the pathogen with a range of antimicrobial compounds, and, at the same time, invoke programmed cell death in cells surrounding the site of infection and changes to structural defenses to produce a barrier against further invasive growth.

A further consequence of local induction of the hypersensitive response is a systemic resistance activated throughout the plant, termed *systemic acquired resistance* (SAR). This has some conceptual similarities to the immune response in animals, in that it is long lasting, and can be boosted by repeat inoculations, but, unlike animal immunity, it can be effective against a range of pathogens, conferring broad spectrum resistance. Salicylic acid is a key signaling molecule in SAR and specific genes such as *PR-1, PR-2,* and *PR-5* are taken as markers for this form of resistance. Interestingly, necrosis-inducing pathogens such as *Alternaria* spp. induce a different systemic defense mechanism characterized by jasmonate and ethylene signaling and different *PR* gene induction, while nonpathogens such as the plant growth – promoting rhizobacteria induce a third type of systemic resistance, induced systemic resistance (ISR). Some components of these different systemic mechanisms overlap, while others are antagonistic, but the overall result appears to be to prime host cells in systemic tissues for a more rapid future deployment of defenses. There is also some evidence that these systemic signals can result in the production of volatile signaling molecules,

such as methyl jasmonates and methyl salicylates, that are detected by adjacent plants to result in a form of ''communal'' resistance.

3.4 Triggers for Induced Resistance

For induction of resistance, plants must be able to recognize and respond to the invading organism. The triggers for this appear to be a group of constitutively produced peptides capable of interacting with and responding to elicitors emanating from the pathogens. In nonhost resistance, these elicitors may be general proteins such as flagellin from bacteria, or oligomers of chitins and glucans from fungi, that the plant recognizes as ''pathogen associated molecular patterns'' (PAMPs), as part of a defense mechanism with similarities to innate immunity (the ability to recognize self from nonself) in animals. However, as mentioned in Sect. 2.3.4, some organisms have evolved the ability to mask these elicitors and/or suppress the defense responses. When this has happened, the second form of induced resistance, host or gene-for-gene resistance may have evolved. Here, the plant encodes specific ''receptors'' that detect the presence of specific elicitors from a pathogen. These elicitors may be individual viral proteins (coat protein, replicase etc.), proteins secreted from bacteria by type III secretion mechanisms, or those secreted through fungal and oomycete haustoria, that the plant has found a way of recognizing. Because they are specific elicitors, they will be encoded by specific genes (referred to as *Avr* genes), and the recognition protein in the plant will similarly be encoded by a specific gene (the *R* gene).

This is the basis for the gene-for-gene concept where resistance will occur as long as the plant has the dominant allele of the specific *R* gene that recognizes the *Avr* gene-encoded elicitor. However, if the plant has no dominant *R* allele, or the pathogen loses this elicitor (through selection and/or mutation), disease will occur, although if the avirulence elicitor is a key component of pathogenicity, loss of function may result in reduced pathogenicity. This, in turn, may result in an evolutionary ''arms race'' developing with complementary changes occurring in the plant and pathogen populations. In natural plant/pathogen ecosystems, this often results in evolutionary stability, but, in agriculture, where resistance is bred into commercial cultivars that are used as extensive monocultures, it can be responsible for severe epidemics if the resistance gene is overcome. There are, however, some *R* genes that have been shown to be highly effective and long lasting in crop protection, and this has led to the concept that *R* genes can be subdivided into those that are that are slow-evolving and presumably recognize elicitors that are essential pathogenicity factors, and those that are rapidly evolving and presumably detect avirulence elicitors that have little fitness penalty on the pathogen.

3.5 The *R* Genes

Because of the genetic simplicity of the gene-for-gene concept, these major resistance genes have been the focus of extensive research to understand the molecular basis of disease resistance. As a result, a significant number of *R* genes have been cloned in the last decade from a number of plant species and against a range of viral, bacterial, fungal, and oomycete pathogens. These genes are often found clustered in the plant genomes as families

residing at complex loci, and the loci may include apparently inactive resistance gene analogs (RGAs), sequences disrupted by frameshifts, mutations, and transposons, and *R* genes capable of recognizing more than one pathogen.

On the basis of their sequences, *R* genes have been grouped into a number of classes, with the largest class encoding a nucleotide binding site plus a carboxy-terminal leucine-rich repeat domain (NBS-LRR). Some of these also possess a domain with toll/interleukin-1-receptor homology (TIR) at their amino terminal (the TNLs), while others have a loosely predicted coiled-coil (CC) domain (the CNLs). A smaller class of resistance genes possess serine-threonine kinase domains either physically linked to an LRR domain (e.g. the *Xa21* gene from rice) or functionally linked (the *Pto* gene from tomato linked to *Prf*). Other smaller classes of resistance genes have more unique characteristics.

The leucine-rich repeat domains, which consist of multiple serial amino acid repeats containing leucines at regular intervals, have similarities to domains in mammalian proteins involved in protein–protein recognition, and it has therefore been postulated that they are involved in recognition of the pathogen elicitors. Evidence to support this comes from domain swaps between resistance genes such as the *L* alleles of flax, where they determine the rust resistance specificity, although in some cases regions of the NBS also appear to be important. The predicted cellular locations of the LRR domains add further support to a role in recognition. Those that detect apoplastic fungi, such as *C. fulvum*, have an extracellular location, while most others have a cytoplasmic location in which they are most likely to detect viruses, bacterial effector proteins, and secreted fungal peptides.

Attempts to confirm that R proteins interact directly with avirulence proteins have, however, been less conclusive. The rice Pi-ta protein has been shown to interact with the rice blast Avr-Pita protein in yeast two-hybrid experiments, but in most other cases such interactions have not been found. Furthermore, the bacterial effector protein AvrPto interacts with the Pto resistance protein of tomato, which has no LRR domain. A proposed model to account for this is the ''Guard hypothesis'' in which the LRR-type resistance proteins (in the case of AvrPto/Pto, this might be Prf) is there to guard a key plant protein and to detect the interaction between this and the pathogen elicitor. Further evidence that R protein/Avr protein recognition involves a number of other protein–protein interactions come from studies on *Pseudomonas syringae* and *Arabidopsis*. Here, a protein Rin4 has been shown to interact with AvrB and AvrRPM1, and also with the resistance gene product RPM1 that recognizes both of these avirulence peptides genetically. The Rin4 protein also interacts with a separate resistance gene protein RPS2, but in an inhibitory way such that removal of Rin4 when the complementary avirulence peptide AvrRPt2 is present results in RPS2 activation. This clearly indicates that R protein/Avr protein interactions are often more complex than a simple ''receptor''/ligand model, and involve multiple protein/protein interactions.

3.6 Downstream Signaling of Resistance

The other domains present in resistance gene proteins are predicted to have functions in the signaling that results in the HR (see Sect. 3.3). Protein kinases have known roles in signaling. TIR domains

have homology to the cytoplasmic signaling domains of the *Drosophila* toll protein and interleukin-1-receptors of birds and animals, which are part of the innate immune response, while NBS domains have ATP- or GTP-binding activities that regulate protein–protein interactions and occur in apoptosis proteins such as APAF-1 (apoplastic protease activation factor) in humans and CED-4 (*Caenorhabditis elegans* death regulator protein 4) in *C. elegans*.

To identify components of *R* gene signaling pathways, genetic analysis, particularly in *Arabidopsis*, has been important. Mutants have been identified, for example, with increased susceptibility, or deficiencies in pathogen-induced phytoalexin accumulation, and these have been mapped on to signaling pathways. Figure 4 indicates a simplified scheme for how these signaling pathways proposed in plant defense responses overlap to culminate in changes in gene expression, programmed cell death, and systemic signaling.

As in all eukaryotes, MAPKs are key signaling components involved in regulating target gene expression in response to signals, and specific MAPKKK, MAPKK, MAPK, and WRKY-type transcription factors have been identified associated with some signaling cascades such as that involved in the flagellin receptor FLS2. In addition, one of the most rapid measurable changes that occurs to a plant during the hypersensitive response is a large transient ion flux across plasma membranes, in particular, K^+ efflux and Ca^{2+} influx. Resistance genes interacting with elicitors directly or indirectly are thought to modulate this through G-protein signaling cascades operating through phospholipase C, diacylglycerol (DAG), and inositol 1,4,5-triphosphate (IP_3), and this in turn activates kinase-signaling cascades to regulate target gene expression.

Along with calcium fluxes, reactive oxygen species (ROS) are rapidly induced as part of HR via NADPH/NADH oxidases or via apoplastic peroxidases. The resultant hydrogen peroxide may have direct antimicrobial affects, but is more likely to be involved in signaling, activating MAPK cascades, interacting with NO signaling, and setting off systemic defense responses. In addition, the hydrogen peroxide reacts through the Fenton cycle of reactions with intracellular transition metals to form the hydroxyl radical, which causes DNA fragmentation and cell damage, both in the invading pathogen and in plant cells to form a barrier against further pathogen ingress. Reactive oxygen species may also have a role in regulating protein turnover; proteins with CHORD (cysteine and histidine rich) domains, such as RAR1 in barley, have been identified in defense responses with proposed roles in coordinating the degradation and turnover of proteins involved in defense signaling. RAR1 interacts with the protein SGT1, which regulates a group of RING-type E3 ubiquitin ligases. These are the specificity determinants that mediate transfer of ubiquitin to target proteins, which undergo degradation at the 26S proteasome. However, it is not yet known which proteins are the targets for this process in defense responses. ROSs also work in conjunction with NO to regulate plant cell apoptosis and signaling, and NO may also interact with oxygen to form peroxynitrite, which has direct antimicrobial properties.

Downstream, low molecular weight signaling molecules such as salicylic acid and jasmonic acid are produced and are involved in both local and systemic resistance responses. Salicylic acid is synthesized from chorismate in plants by two pathways, one involving phenylalanine and the enzyme phenylalanine ammonia lyase

(PAL), which is known to be upregulated as part of HR. The other pathway involves isochorismate synthase, which has been identified in *Arabidopsis* through mutant screens for enhanced disease susceptibility. Jasmonic acid is synthesized by plasma membrane–located lipases, which are believed to be induced by calcium fluxes.

Three key components identified as part of these downstream signaling pathways are EDS1, NDR1, and NPR1. EDS1 has been mapped onto TNL-type resistance pathways and is required, both for HR development and in association with PAD4, for salicylic acid accumulation. NDR1, which has been identified as a transmembrane protein, appears to be involved in CNL-type resistance. Both these pathways converge at NPR1, which is an ankyrin-repeat protein that interacts with transcription factors of the TGA type of basic leucine zippers. These, in turn, appear to bind to the promoter elements upstream of *PR*-protein genes to regulate their expression. Induced systemic resistance also appears to require the NPR1 protein, but uses jasmonates and ethylene as the signals, while the systemic pathways from necrosis-inducing pathogens are independent of NPR1 and may be mutually antagonistic to act through plant defensins and thionins.

3.7 Coordination of Defense Responses

The coordination of these signaling pathways to result in defense responses is complex and, like in animal systems, is believed to involve the mitochondria. In animals, the mitochondria interprets and amplifies stress signals such as calcium fluxes, ion fluxes, ROS, NO, and so on, to result in release from the mitochondrion of cell death activators, inhibitors, and inhibitor derepressors such as cytochrome *c* to regulate apoptosis proteins, caspase cascades, and cell death. In plants, however, there is limited evidence for the involvement of cytochrome *c*, and the caspase-like proteins identified are not direct homologs of those in animals. It has been proposed that this lack of conservation is related to the way that defense responses manifest themselves in plants and animals. In animals, programmed cell death has to be strictly controlled to be rapid and to ensure that the dead cells are removed to prevent inflammation of adjacent cells. In plants, however, the same evolutionary constraints do not apply and a form of programmed oncosis appears to occur where spread to adjacent cells can act to the advantage of the plant by forming a barrier of dead cells through which the pathogen cannot grow.

4 Concluding Remarks

Much has been learnt about the molecular basis of disease resistance in plants and about the mechanisms of fungal, oomycete, bacterial, and viral pathogenicity. The dynamic coevolutionary processes have resulted in multiple facets to the mechanisms, with microbes acquiring pathogenicity factors so that they can colonize plants, plants evolving a complex battery of defensive mechanisms, pathogens developing ways to evade these, and plants developing further layers of resistance. Added to the general mechanisms that have been discussed, there are also examples of resistance conferred by recessive genes, such as the barley *mlo* gene for resistance to powdery mildew, and there are also many cases where resistance

is controlled quantitatively by polygenic resistance mechanisms, and our knowledge of the molecular basis of this form of resistance is in its infancy.

From a practical perspective, understanding the molecular basis of plant–pathogen interactions has a range of applications in crop protection. Molecular diagnostics for detection and identification of organisms can be developed to supplement and enhance traditional diagnostic techniques, and can be used to ensure that appropriate and targeted crop protection strategies are used. Molecular markers linked to traits such as resistance genes can be used in breeding programs to improve commercial cultivars. Molecular genetics can also help with the identification of new resistance genes. Specific target elicitors from pathogens can be screened on different accessions and wild relatives of crop plants using transient expression vectors to identify new sources of resistance for breeding into commercial cultivars. Alternatively, DNA shuffling techniques could be used to create large numbers of recombinant resistance genes from cloned resistance genes and resistance gene analogs, and these could be screened for new specificities.

There are also many technically feasible and tested approaches for controlling disease through the genetic modification of plants, using methods such as pathogen-derived resistance, overexpression of defense-related genes or cloned resistance genes. For example, viral coat protein genes have been introduced into plants to give effective pathogen-derived resistance against many viruses, and the *Xa21* gene for rice resistance to *Xanthomonas oryzae* has been transferred at the Rice Research Institute in the Philippines from the wild species *Oryzae longistaminata* into elite cultivars, a process that has been difficult to achieve through conventional breeding.

Whether molecular biology will be used in the future primarily to support conventional crop protection methods or for the genetic modification of plants will depend on public acceptance and government policies. Appropriate deployment is also crucial to ensure that such techniques do not simply perpetuate the development of new ''super-pathogens'' capable of overcoming the control methods. However, there is no doubt that the use of molecular biology has dramatically increased our understanding of plant-pathogen interactions and will continue to do so as the functions of more genes and gene products are identified in both pathogenicity and resistance mechanisms.

Keywords

GMP
Good Manufacturing Practice (GMP) was established by WHO in 1968 to guarantee the optimum degree of quality during production and processing of pharmaceuticals (cGMP means under the current regulations of the authorities).

Transgenic
Organisms that have externally introduced foreign DNA/genes stably integrated into their genome to, for example, produce desired substances like human insulin.

Plant-based Expression
Transgenic plants can be genetically modified with a gene of interest to produce a biopharmaceutical of interest.

Glycosylation
It is the addition of polysaccharides to a certain molecule such as a protein. The majority of proteins are synthesized in the rough endoplasmic reticulum (ER) where they undergo glycosylation.

Bioreactor
It is a vessel in which a (bio)chemical process that involves organisms or biochemically active substances (e.g. enzymes) derived from such organisms is carried out.

Biopharmaceuticals are currently the mainstay products of the biotechnology market and represent the fastest growing and, in many ways, the most exciting sector within the pharmaceutical industry. The term ''biopharmaceutical'' was originated in the 1980s, when a general consensus evolved that it represented a class of therapeutics produced by means of modern biotechnologies. Already a quarter of a century ago, ''humulin'' (recombinant human insulin, produced in *E. coli* and developed by Genentech in collaboration with Eli Lilly) was approved and received marketing authorization in the United States of America in 1982. Since then the market for biopharmaceuticals has been steadily growing and currently nearly 150 biopharmaceuticals have gained approval for general human use (EU and USA). Over this period it became obvious that production capacities for biopharmaceuticals with ''conventional'' bioreactors would be a bottleneck and that worldwide fermentation capacities are limited. One exciting solution to these ''capacity crunches'' is the use of transgenic plants to produce biopharmaceuticals. This article describes different plant expression systems, their advantages and limitations, and concludes by considering some of the innovations and trends likely to influence the future of plant-based biopharmaceuticals.

1 Introduction

Biopharmaceuticals, which are large molecules produced by living cells, are currently the mainstay products of the biotechnology industry. Indeed, biologics such as Genentech's (Vacaville, CA, USA) human growth factor somatropin or Amgen's (Thousand Oaks, CA, USA) recombinant erythropoietin (EPO) have shown that biopharmaceuticals can benefit a huge number of patients and also generate big profits for these companies at the same time. The single most lucrative product is EPO and combined sales of the recombinant EPO products ''Procrit'' (Ortho biotech) and ''Epogen'' (Amgen) have reportedly surpassed the $6.5 billion mark. But it has also become obvious over the last couple of years that current fermentation capacities will not be sufficient to manufacture all biopharmaceuticals (in the market already or in development), because the market and demand for biologics is continuously and very rapidly growing; for antibodies alone (with at least 10 monoclonal antibodies approved and being marketed), the revenues are predicted to expand to US$3 billion in 2002 and US$8 billion in 2008. The 10 monoclonal antibodies on the market consume more than 75% of the industry's manufacturing capability. And there are up to 60 more that are expected to reach the market in the next six or seven years. Altogether, there are about 1200 protein-based products in the pipeline with a 20% growth rate and the market for current and late stage (Phase III) is estimated to be US$42 billion in 2005 and even US$100 billion in 2010. But, there are obvious limitations of large-scale manufacturing resources and production capacities – and pharmaceutical companies are competing (see ref Knäblein (2004), review).

To circumvent this capacity crunch, it is necessary to look into other technologies rather than the established ones, like, for example, *Escherichia coli* or CHO (Chinese hamster ovary) cell expression. One solution to avoid these limitations could be the use of transgenic plants to express recombinant proteins at low cost, in GMP (good manufacturing practice) quality greenhouses (with purification and fill finish in conventional facilities). Plants therefore provide an economically sound source of recombinant proteins, such as industrial enzymes, and biopharmaceuticals. Furthermore, using the existing infrastructure for crop cultivation, processing, and storage will reduce the amount of capital investment required for commercial production. For example, it was estimated that the production costs of recombinant proteins in plants could be between 10 and 50 times lower than those for producing the same protein in *E. coli* and Alan Dove describes a factor of thousand for cost of protein (US dollar per gram of raw material) expressed in, for example, CHO cells compared to transgenic plants. So, at the dawn of this new millennium, a solution is imminent to circumvent expression capacity crunches and to supply mankind with the medicines we need. Providing the right amounts of biopharmaceuticals can now be achieved by applying our knowledge of modern life sciences to systems that were on this planet long time before us – plants.

2 Alternative Expression Systems

Currently, CHO cells are the most widely used technology in biomanufacturing because they are capable of expressing eukaryotic proteins (processing, folding,

and posttranslational modifications) that cannot be provided by *E. coli*. A long track record exists for CHO cells, but unfortunately they bring some problems along when it comes to scaling up production. Transport of oxygen (and other gases) and nutrients is critical for the fermentation process, as well as the fact that heat must diffuse evenly to all cultured cells. According to the Michaelis–Menten equation, the growth rate depends on the oxygen/nutrient supply; therefore, good mixing and aeration are a prerequisite for the biomanufacturing process and are usually achieved by different fermentation modes (see Fig. 1). But the laws of physics set strict limits on the size of bioreactors. For example, an agitator achieves good heat flow and aeration, but with increased fermenter size, shear forces also increase and disrupt the cells – and building parallel lines of bioreactors multiplies the costs linearly. A 10 000-L bioreactor costs between US$ 250 000 to 500 000 and takes five years to build (conceptual planning, engineering, construction, validation, etc.). An error in estimating demand for, or inaccurately predicting the approval of, a new drug can be incredibly costly. To compound the problem, regulators in the United States and Europe demand that drugs have to be produced for the market in the same system used to produce them for the final round of clinical trials, in order to guarantee bioequivalence (e.g. toxicity, bioavailability, pharmacokinetics, and pharmacodynamics) of the molecule. So, companies have to choose between launching a product manufactured at a smaller development facility (and struggling to meet market demands) or building larger, dedicated facilities for a drug that might never be approved!

Therefore, alternative technologies are used for the expression of biopharmaceuticals, some of them also at lower costs involved (see Fig. 2). One such alternative is the creation of transgenic animals (''pharming''), but this suffers from the disadvantage that it requires a long time to establish such animals (approximately 2 years). In addition to that, some of the human biopharmaceuticals could be detrimental to the mammal's health, when expressed in the mammary glands. This is why ethical debates sometimes arise from the use of transgenic mammals for production of biopharmaceuticals. Although there are no ethical concerns involved with plants, there are societal ones that will be addressed later. Another expression system (see Fig. 2) utilizes transgenic chicken. The eggs, from which the proteins are harvested, are natural protein-production systems. But production of transgenic birds is still

Fig. 2 Companies and technologies in biomanufacturing. A comparison of different expression systems shows the big differences in terms of costs, ranging from 150 US$ per gram for CHO cells to 0.05 US$ per gram for transgenic plants. Source: Dove, A. (2002) Uncorking the biomanufacturing bottleneck, *Nat. Biotechnol.* **20**, 777–779.

several years behind transgenic mammal technology. Intensive animal housing constraints also make them more susceptible to disease (e.g. Asia 1997 or Europe 2003: killing of huge flocks with thousands of chicken suffering from fowl pest). In the light of development time, experience, costs, and ethical issues, plants are therefore the favored technology, since such systems usually have short gene-to-protein times (weeks), some are already well established, and as mentioned before, the involved costs are comparatively low. This low cost of goods sold (COGS) for plant-derived proteins is mainly due to low capital costs: greenhouse costs are only US$ 10 per m^2 versus US$ 1000 per m^2 for mammalian cells.

3 History of Plant Expression

Plants have been a source of medicinal products throughout human evolution. These active pharmaceutical compounds have been primarily small molecules, however. One of the most popular examples is aspirin (acetylsalicylic acid) to relieve pain and reduce fever. A French pharmacist first isolated natural salicin (a chemical relative of the compound used to make aspirin) from white willow bark in 1829. Advances in genetic engineering are now allowing for the production of therapeutic proteins (as opposed to small molecules) in plant tissues. Expression of recombinant proteins in plants has been well documented since the 1970s and has slowly gained credibility in the biotechnology industry and regulatory agencies. The first proof of concept has been the incorporation of insect and pest resistance into grains. For example, ''Bt corn'' contains genes from *Bacillus thuringensis* and is currently being grown commercially. Genetic engineering techniques are now available for the manipulation of almost all commercially valuable plants. Easy transformation and cultivation make plants suitable

for production of virtually any recombinant protein.

Plants have a number of advantages over microbial expression systems, but one of them is of outmost importance: they can produce eukaryotic proteins in their native form, as they are capable of carrying out posttranslational modifications required for the biological activity of many such proteins (see Fischer Schillberg (2004), books). These modifications can be acetylation, phosphorylation, and glycosylation, as well as others. Per se, there is no restriction to the kind of proteins that can be expressed in plants: vaccines (e.g. pertussis or tetanus toxins), serum proteins (e.g. albumin), growth factors (e.g. vascular endothelial growth factor (VEGF), erythropoietin), or enzymes (e.g. urokinase, glucose oxidase, or glucocerebrosidase). However, enzymes sometimes have very complex cofactors, which are essential for their catalytic mode of action, but cannot be supplied by most expression systems. This is why, for the expression of some enzymes, expression systems with special features and characteristics need to be developed. Another very important class of proteins is the antibodies (e.g. scFv, Fab, IgG, or IgA). More than 100 antibodies are currently used in clinical trials as therapeutics, drug delivery vehicles, in diagnostics and imaging, and in drug discovery research for both screening and validation of targets. Again, plants are considered as the system of choice for the production of antibodies (''plantibodies'') in bulk amounts at low costs. Since the initial demonstration that transgenic tobacco (*Nicotiana tabacum*) is able to produce functional IgG1 from mouse, full-length antibodies, hybrid antibodies, antibody fragments (Fab), and single-chain variable fragments (scFv) have been expressed in higher plants for a number of purposes. These antibodies can serve in health care and medicinal applications, either directly by using the plant as a food ingredient or as a pharmaceutical or diagnostic reagent after purification from the plant material. In addition, antibodies may improve plant performance, for example, by controlling plant disease or by modifying regulatory and metabolic pathways.

4
Current Status of Plant-based Expression

4.1
SWOT Analysis Reveals a Ripe Market for Plant Expression Systems

When I analyzed the different expression systems regarding their strengths, weaknesses, opportunities, and threats (SWOT), the advantages of plants and their potential to circumvent the worldwide capacity limitations for protein production became quite obvious (see Fig. 3). Comparison of transgenic animals, mammalian cell culture, plant expression systems, yeast, and bacteria shows certain advantages for each of the systems. In the order in which the systems were just mentioned, we can compare them in terms of their development time (speed). Transgenic animals have the longest cycle time (18 months to develop a goat), followed by mammalian cell culture, plants, yeast, and bacteria (one day to transform *E. coli*). If one looks at operating and capital costs, safety, and scalability, the data show that plants are beneficial: therefore, in the comparison (see Fig. 3), they are shown on the right-hand side already. But even for glycosylation, multimeric assembly and folding (where plants are not shown on the right-hand side, meaning other systems are advantageous), some plant expression systems are moving in

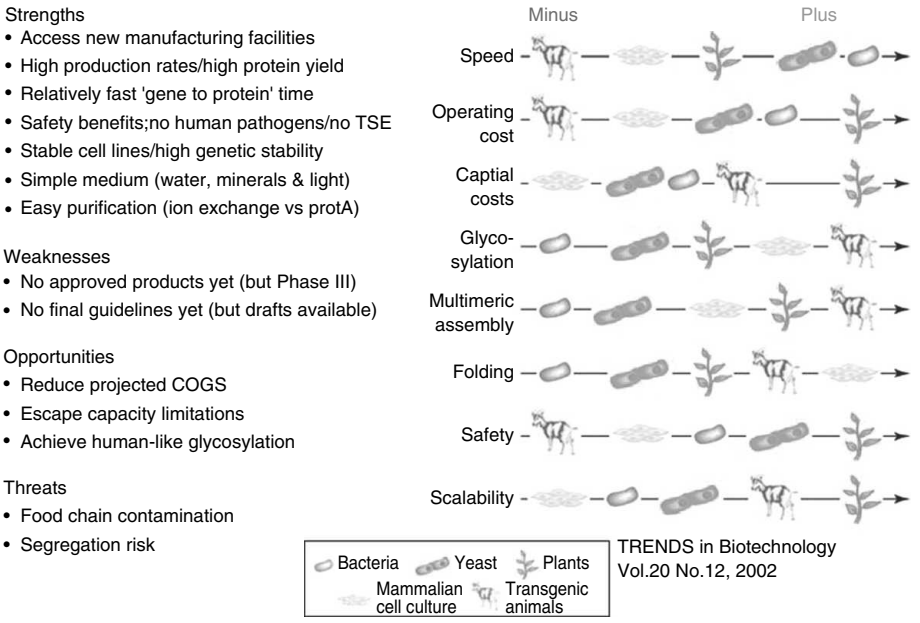

Fig. 3 SWOT analysis of plant expression systems. Plant expression systems have a lot of advantages (plus) over other systems and are therefore mostly shown on the right-hand side of the picture (Raskin, I., Fridlender, B., et al. (2002) Plants and human health in the twenty-first century, *Trends Biotechnol.* **20**, 522–531). Herein different systems (transgenic animals, mammalian cell culture, plants, yeast, and bacteria) are compared in terms of speed (how quickly they can be developed), operating and capital costs, and so on, and plants are obviously advantageous. Even for glycosylation, assembly, and folding, where plants are not shown on the right-hand side (meaning other systems are advantageous), some plant expression systems are moving in that direction (as will be shown exemplarily in the section on moss). Also the weaknesses and threats can be dealt with, using the appropriate plant expression system. Source: Knäblein J. (2003) *Biotech: A New Era In The New Millennium – From Plant Fermentation To Plant Expression Of Biopharmaceuticals*, PDA International Congress, Prague, Czech Republic.

that direction. An example of this is the moss system from the company greenovation Biotech GmbH (Freiburg, Germany), which will be discussed in detail in the example section. This system performs proper folding and assembly of even such complex proteins like the homodimeric VEGF. Even the sugar pattern could successfully be reengineered from plant to humanlike glycosylation.

In addition to the potential of performing human glycosylation, plants also enjoy the distinct advantage of not harboring any pathogens, which are known to harm animal cells (as opposed to animal cell cultures and products), nor do the products contain any microbial toxins, TSE (Transmissible Spongiform Encephalopathies), prions, or oncogenic sequences. In fact, humans are exposed to a large, constant dose of living plant viruses in the diet without any known effects/illnesses. Plant production of protein therapeutics also has advantages with regard to their scale and speed of production. Plants can be grown in ton quantities (using

existing plant/crop technology, like commercial greenhouses), be extracted with industrial-scale equipment, and produce kilogram-size yields from a single plot of cultivation. These economies of scale are expected to reduce the cost of production of pure pharmaceutical-grade therapeutics by more than 2 orders of magnitude versus current bacterial fermentation or cell culture reactor systems (plus raw material COGS are estimated to be as low as 10% of conventional cell culture expenses).

Although a growing list of heterologous proteins were successfully produced in a number of plant expression systems with their manifold advantages, there are also obvious downsides. One weakness is that no product has been approved for the market yet (but will be soon, since some are in Phase III clinical trials already, see Table 1). The other weakness is that no final regulatory guidelines exist. But as mentioned before, regulatory authorities (Food and Drug Administration (FDA), European Medicine Evaluation Agency (EMEA), and Biotechnology Regulatory Service (BRS) and the Biotechnology Industry Organization (BIO) have drafted guidelines on plant-derived biopharmaceuticals (see Table 2) and have asked the community for comments. The FDA has also issued several PTC (Points To Consider) guidelines about plant-based biologics, and review of the July 2002 PTC confirms that the FDA supports this field and highlights the benefits of plant expression systems – including the absence of any pathogens to man from plant extracts. The main concerns of using plant expression systems are societal ones about environmental impacts, segregation risk, and contamination of the food chain. But these threats can be dealt with, using nonedible plants (nonfood, nonfeed), applying advanced containment technologies (GMP greenhouses, bioreactors) and avoiding open-field production.

Owing to the obvious strengths of plant expression systems, there has been explosive growth in the number of start-up companies. Since the 1990s, a number of promising plant expression systems have been developed, and in response to this ''blooming field'' big pharmaceutical companies have become more interested. Now, the plant expression field is ''ripe'' for strategic alliances, and, in fact, the last year has seen several major biotech companies begin partnerships with such plant companies. The selection of several such partnerships shown in Table 1 clearly demonstrates that, in general, there has been sufficient experimentation with various crops to provide the overall proof of concept that transgenic plants can produce biopharmaceuticals. However, and this can be seen in the table as well, the commercial production of biopharmaceuticals in transgenic plants is still in the early stages of development and yet the most advanced products are in Phase III clinical development.

4.2 Risk Assessment and Contingency Measures

For a number of reasons, including the knowledge base developed on genetically modifying its genome, industrial processes for extracting fractionated products and the potential for large-scale production, the preferred plant expression system has been corn. However, the use of corn touches on a potential risk: some environmental activist groups and trade associations are concerned about the effect on the environment and possible contamination of the food supply. These issues

are reflected in the regulatory guidelines and have been the driving force to investigate other plants as well. While many mature and larger companies have been working in this area for many years, there are a number of newcomers that are developing expertise as well. These smaller companies are reacting to the concerns by looking at the use of nonedible plants that can be readily raised in greenhouses. All potential risks have to be assessed and contingency measures need to be established. Understanding the underlying issues is mandatory to make sophisticated decisions about the science and subsequently on the development of appropriate plant expression systems for production of biopharmaceuticals.

Ongoing public fears from the food industry and the public, particularly in Europe (''Franken Food'') could have spillover effects on plant-derived pharmaceuticals. Mistakes and misunderstandings have already cost the genetically enhanced grain industry hundreds of millions of dollars. The only way to prevent plant expression systems from suffering the same dilemma is to provide the public with appropriate information on emerging discoveries and newly developed production systems for biopharmaceuticals. Real and theoretical risks involve the spread of engineered genes into wild plants, animals, and bacteria (horizontal transmission). For example, if herbicide resistance was transmitted to weeds, or antibiotic resistance was to be transmitted to bacteria, superpathogens could result. If these genetic alterations were transmitted to their progeny (vertical transmission), an explosion of the pathogens could cause extensive harm. An example of this occurred several years ago, when it was feared that pest-resistant genes had been transmitted from Bt corn to milkweed – leading to the widespread death of Monarch butterflies. Although this was eventually not found to be the case, the public outcry over the incident was a wake-up call to the possible dangers of transgenic food technology. To avoid the same bad perception for biopharmaceuticals expressed in plants, there is the need for thorough risk assessment and contingency planning. One method is the employment of all feasible safety strategies to prevent spreading of engineered DNA (genetic drift), like a basic containment in a greenhouse environment. Although no practical shelter can totally eradicate insect and rodent intrusion, this type of isolation is very effective for self-pollinators and those plants with small pollen dispersal patterns. The use of species-specific, fragile, or poorly transmissible viral vectors is another strategy. Tobacco mosaic virus (TMV), for example, usually only infects a tobacco host.

It requires an injury of the plant to gain entry and cause infection. Destruction of a field of TMV-transformed tobacco requires only plowing under or application of a herbicide. These factors prevent both horizontal and vertical transmission. In addition, there is no known incidence of plant viruses infecting animal or bacterial cells. Another approach is to avoid stable transgenic germlines and therefore most uses of transforming viruses do not involve the incorporation of genes into the plant cell nucleus. By definition, it is almost impossible for these genes to be transmitted vertically through pollen or seed. The engineered protein product is produced only by the infected generation of plants. Another effective way to reduce the risk of genetic drift is the use of plants that do not reproduce without human aid. The modern corn plant cannot reproduce without cultivation and

the purposeful planting of its seeds. If a plant may sprout from grain, it still needs to survive the wintering-over process and gain access to the proper planting depth. This extinction process is so rapid, however, that the errant loss of an ear of corn is very unlikely to grow a new plant. Another very well-known example of self-limited reproduction is the modern banana. It propagates almost exclusively through vegetative cloning (i.e. via cuttings).

Pollination is the natural way for most plants to spread their genetic information, make up new plants, and to deliver their offspring in other locations. The use of plants with limited range of pollen dispersal and limited contact with compatible wild hosts therefore is also very effective to prevent genetic drift. Corn, for example, has pollen, which survives for only 10 to 30 min and, hence, has an effective fertilizing radius of less than 500 m. In North America, it has no wild-type relatives with which it could cross-pollinate. In addition to being spatially isolated from nearby cornfields, transgenic corn can be ''temporally isolated'' by being planted at least 21 days earlier or 21 days later than the surrounding corn, to ensure that the fields are not producing flowers at the same time. Under recent USDA (U.S. Department of Agriculture) regulations, the field must also be planted with equipment dedicated to the genetically modified crop. For soybeans, the situation is different, since they are virtually 100% self-fertilizers and can be planted in very close proximity to other plants without fear of horizontal spread. Another option is the design of transgenic plants that have only sterile pollen or – more or less only applicable for greenhouses – completely prevent cross-pollination by covering the individual plants. One public fear regards spreading antibiotic resistance from one (transgenic donor) plant to other wild-type plants or bacteria in the environment. Although prokaryotic promoters for antibiotic resistance are sometimes used in the fabrication and selection of transgenic constructs, once a transgene has been stably incorporated into the plant genome, it is under the control of plant (eukaryotic) promoter elements. Hence, antibiotic-resistance genes are unable to pass from genetically altered plants into bacteria and remain functional. As stated earlier, another common fear is the creation of a ''super bug.'' The chance of creating a supervirulent virus or bacterium from genetic engineering is unlikely, because the construction of expression cassettes from viral or bacterial genomes involves the removal of the majority of genes responsible for the normal function of these organisms. Even if a resultant organism is somewhat functional, it cannot compete for long in nature with normal, wild-type bacteria of the same species.

As one can see from the aforementioned safety strategies, considerable effort is put into the reduction of any potential risk from the transgenic plant for the environment. In general, the scientific risk can be kept at a minimum, if common sense is applied – in accordance with Thomas Huxley (1825–1895) that ''Science is simply common sense at its best.'' For example, protein toxins (for vaccine production) should never be grown in food plants.

Additionally, the following can be employed as a kind of risk management to prevent the inappropriate or unsafe use of genetically engineered plants:

- An easily recognized phenotypic characteristic can be coexpressed in an

engineered product (e.g. tomatoes that contain a therapeutic protein can be selected to grow in a colorless variety of fruit).

- Protein expression can be induced only after harvesting or fruit ripening. For example, CropTech's (Blacksburg, VA, USA) inducible expression system in tobacco, MeGA-PharM, leads to very efficient induction upon leaf injury (harvest) and needs no chemical inducers. This system possesses a fast induction response and protein synthesis rate, and thus leads to high expression levels with no aged product in the field (no environmental damage accumulation).
- Potentially antigenic or immunomodulatory products can be induced to grow in, or not to grow in, a certain plant tissue (e.g. root, leaf/stem, seed, or pollen). In this way, for example, farmers can be protected from harmful airborne pollen or seed dusts.
- Although no absolute system can prevent vandalism or theft of the transgenic plants, a very effective, cheap solution has been used quietly for many years now in the United States. Plots of these modified plants are being grown with absolutely no indication that they are different from a routine crop. In the Midwest, for example, finding a transgenic corn plot among the millions of acres of concurrently growing grain is virtually impossible. The only question here is, if this approach really helps facilitating a fair and an open discussion with the public. Asking the same question for the EU is not relevant: owing to labeling requirements, this approach would not be feasible, as, in general, it is much more difficult to perform open-field studies with transgenic plants.

5 The Way Forward: Moving Plants to Humanlike Glycosylation

As discussed earlier, plant production of therapeutic proteins has many advantages over bacterial systems. One very important feature of plant cells is their capability of carrying out posttranslational modifications. Since they are eukaryotes (i.e. have a nucleus), plants produce proteins through an ER (endoplasmatic reticulum) pathway, adding sugar residues also to the protein – a process called *glycosylation*. These carbohydrates help determine the three-dimensional structures of proteins, which are inherently linked to their function and their efficacy as therapeutics. This glycosylation also affects protein bioavailability and breakdown of the biopharmaceutical; for example, proteins lacking terminal sialic acid residues on their sugar groups are often targeted by the immune system and are rapidly degraded. The glycosylation process begins by targeting the protein to the ER. During translation of mRNA (messenger RNA) into protein, the ribosome is attached to the ER, and the nascent protein fed into the lumen of the ER as translation proceeds. Here, one set of glycosylation enzymes attaches carbohydrates to specific amino acids of the protein. Other glycosylation enzymes either delete or add more sugars to the core structures. This glycosylation process continues into the Golgi apparatus, which sorts the new proteins, and distributes them to their final destinations in the cell (see Fig. 4). Bacteria lack this ability and therefore cannot be used to synthesize proteins that require glycosylation for activity. Although plants have a somewhat different system of protein glycosylation from mammalian cells, the differences usually prove not to be a problem. Some proteins, however, require

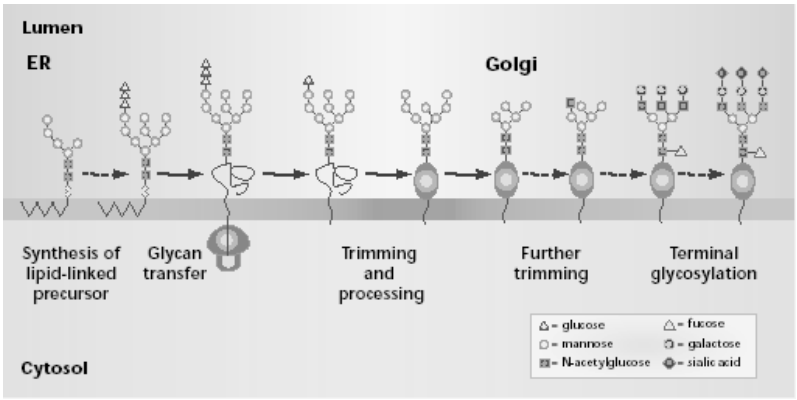

Fig. 4 The glycosylation pathway via ER and Golgi apparatus. In the cytosol, carbohydrates are attached to a lipid precursor, which is then transported into the lumen of the ER to finish core glycosylation. This glycan is now attached to the nascent, folding polypeptide chain (which is synthesized by ribosomes attached to the cytosolic side of the ER from where it translocates into the lumen) and subsequently trimmed and processed before it is folded and moved to the Golgi apparatus. Capping of the oligosaccharide branches with sialic acid and fucose is the final step on the way to a mature glycoprotein. Source: Dove, A. (2001) The bittersweet promise of glycobiology, *Nat. Biotechnol.* **19**, 913–917.

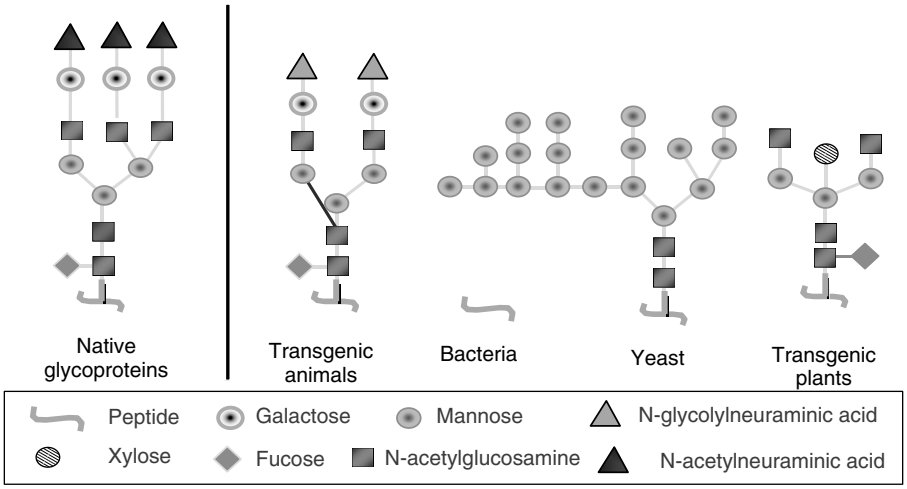

Fig. 5 Engineering plants to humanlike glycosylation. The first step to achieve humanlike glycosylation in plants is to eliminate the plant glycosylation pattern, that is, the attachment of β 1–2 linked xylosyl- and α 1–3 linked fucosyl sugars to the protein. Because these two residues have allergenic potential, the corresponding enzymes Xylosyl- and Fucosyl Transferase are knocked out. In case galactose is relevant for the final product, Galactosyl Transferase is inserted into the host genome. Galactose is available in the organism so that this single gene insertion is sufficient to ensure galactosylation. Source: Knäblein J. (2003) *Biotech: A New Era In The New Millennium – Biopharmaceutic drugs manufactured in novel expression systems*, DECHEMA-Jahrestagung der Biotechnologen, Munich, Germany, 21.

humanlike glycosylation (see Fig. 5) – they must have specific sugar structures attached to the correct sites on the molecule to be maximally effective. Therefore, some efforts are being made in modifying host plants in such a way that they provide the protein with human glycosylation patterns. One example of modifying a plant expression system in this way is the transgenic moss, which will be discussed in the next section.

6 Three Promising Examples: Tobacco (Rhizosecretion, Transfection) and Moss (Glycosylation)

To further elaborate on improving glycosylation and downstream processing, three interesting plant expression systems will be discussed. All systems share the advantage of utilizing nonedible plants (nonfood and nonfeed) and can be kept in either a greenhouse or a fermenter to avoid any segregation risk. Another obvious advantage is secretion of the protein into the medium so that no grinding or extraction is required. This is very important in light of downstream processing: protein purification is often as expensive as the biomanufacturing and should never be underestimated in the total COGS equation.

6.1 Harnessing Tobacco Roots to Secrete Proteins

Phytomedics (Dayton, NJ, USA) uses tobacco plants as an expression system for biopharmaceuticals. Besides the advantage of being well characterized and used in agriculture for some time, tobacco has a stable genetic system, provides high-density tissue (high protein production), needs only simple medium, and can be kept in a greenhouse (see Fig. 6). Optimized antibody expression can be rapidly verified using transient expression assays (short development time) in the plants before creation of transgenic suspension cells or stable plant lines (longer development time). Different vector systems, harboring targeting signals for subcellular compartments, are constructed in parallel and used for transient expression. Applying this screening approach, high expressing cell lines can rapidly be identified. For example, transgenic tobacco plants, transformed with an expression cassette containing the GFP (Green Fluorescent Protein) gene fused to an *aps* (amplification-promoting sequence), had greater levels of corresponding mRNAs and expressed proteins compared to transformants lacking *aps*. Usually, downstream processing (isolation/extraction and purification of the target protein) is limiting for such a system, for example, if the protein has to be isolated from biochemically complex plant tissues (e.g. leaves), this can be a laborious and expensive process and a major obstacle to large-scale protein manufacturing. To overcome this problem, secretion-based systems utilizing transgenic plant cells or plant organs aseptically cultivated *in vitro* would be one solution. However, *in vitro* systems can be expensive, slow growing, unstable, and relatively low yielding. This is why another interesting route was followed. Secretion of molecules is a basic function of plant cells and organs in plants, and is especially developed in plant roots. In order to take up nutrients from the soil, interact with other soil organisms, and defend themselves against numerous pathogens, plant roots have evolved sophisticated mechanisms based on the secretion of different biochemicals (including proteins

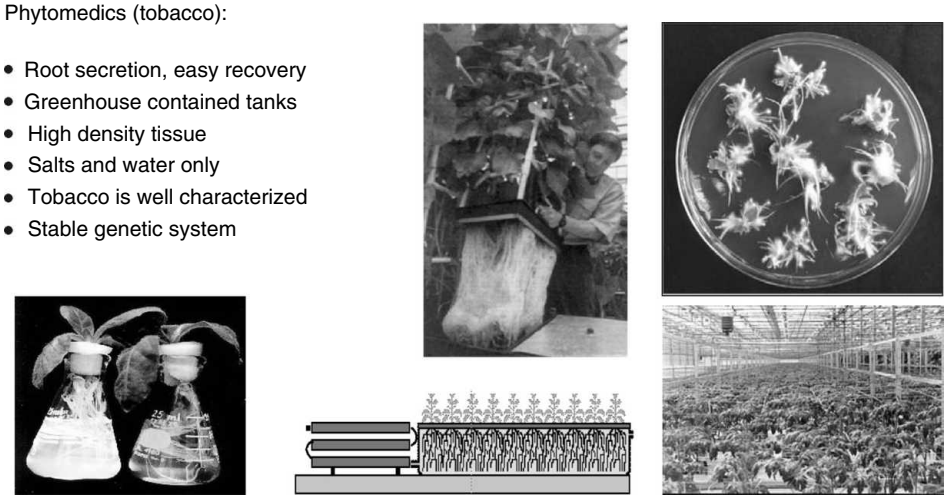

Fig. 6 Secretion of the biopharmaceuticals via tobacco roots. The tobacco plants are genetically modified in such a way that the protein is secreted via the roots into the medium (''rhizosecretion''). In this example, the tobacco plant takes up nutrients and water from the medium and releases GFP (Green Fluorescent Protein). Examination of root cultivation medium by its exposure to near ultraviolet-illumination reveals the bright green-blue fluorescence characteristics of GFP in the hydroponic medium (left flask in panel lower left edge). The picture also shows a schematic drawing of the hydroponic tank, as well as tobacco plants at different growth stages, for example, callus, fully grown, and greenhouse plantation. Source: Knäblein J. (2003) *Biotech: A New Era in the New Millennium – Biopharmaceutic Drugs Manufactured in Novel Expression Systems*, DECHEMA-Jahrestagung der Biotechnologen, Munich, Germany, 21. (See color plate. p. xxv)

like toxins) into their neighborhood (rhizosphere). In fact, Borisjuk and coworkers could demonstrate that root secretion can be successfully exploited for the continuous production of recombinant proteins in a process termed ''*rhizosecretion*.'' Here, an endoplasmic reticulum signal peptide is fused to the recombinant protein, which is then continuously secreted from the roots into a simple hydroponic medium (based on the natural secretion from roots of the intact plants). The roots of the tobacco plant are sitting in a hydroponic tank (see Fig. 6), taking up water and nutrients and continuously releasing the biopharmaceutical. By this elegant set up, downstream processing becomes easy and cost-effective, and also offers the advantage of continuous protein production that integrates the biosynthetic potential of a plant over its lifetime and might lead to higher protein yields than single-harvest and extraction methods. Rhizosecretion is demonstrated in Fig. 6, showing a transgenic tobacco plant expressing GFP and releasing it into the medium.

6.2 High Protein Yields Utilizing Viral Transfection

ICON Genetics (Halle, Germany) has developed a protein-production system that relies on rapid multiplication of viral vectors in an infected tobacco plant (see Fig. 7). Viral transfection systems offer

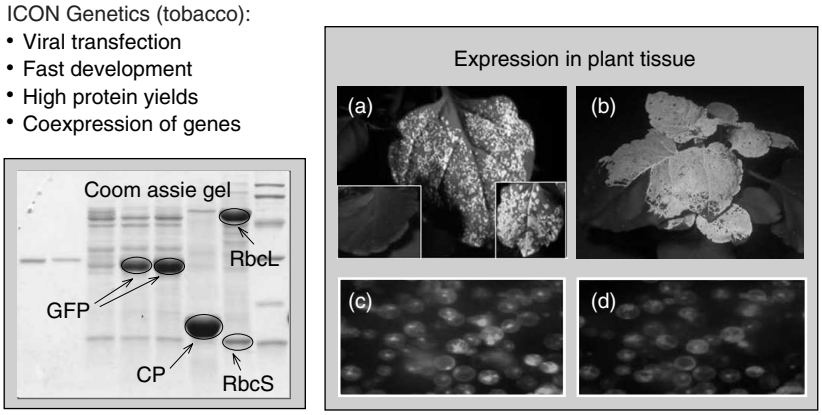

Fig. 7 Viral transfection of tobacco plants. This new generation platform for fast (1 to 2 weeks), high-yield (up to 5 g kg^{-1} fresh leaf weight) production of biopharmaceuticals is based on proviral gene amplification in a nonfood host. Antibodies, antigens, interferons, hormones, and enzymes could successfully be expressed with this system. The picture shows development of initial symptoms on a tobacco following the Agrobacterium-mediated infection with viral vector components that contain a GFP gene (a); this development eventually leads to a systemic spread of the virus, literally converting the plant into a sack full of protein of interest within two weeks (b). The system allows to coexpress two proteins in the same cell, a feature that allows expression of complex proteins such as full-length monoclonal antibodies. Panels (c) and (d) show the same microscope section with the same cells, expressing Green Fluorescent Protein (c) and Red Fluorescent Protein (d) at the same time. The yield and total protein concentration achievable are illustrated by a Coomassie gel with proteins in the system: GFP (protein of interest), CP (coat protein from wild-type virus), RbcS and RbcL (small and large subunit of ribulose-1,5-bisphosphate carboxylase). Source: Knäblein J. (2003) *Biotech: A New Era in the New Millennium – Biopharmaceutic Drugs Manufactured in Novel Expression Systems*, DECHEMA-Jahrestagung der Biotechnologen, Munich, Germany, 21. (See color plate. p. xxv)

a number of advantages, such as very rapid (1 to 2 week) expression time, possibility of generating initial milligram quantities within weeks, high expression levels, and so on. However, the existing viral vectors, such as TMV-based vectors used by, for example, Large Scale Biology Corp. (Vacaville, CA, USA) for production of single-chain antibodies for treatment of non-Hodgkin lymphoma (currently in Phase III clinical trials, see Table 1), had numerous shortcomings, such as inability to express genes larger than 1 kb, inability to coexpress two or more proteins (a prerequisite for production of monoclonal antibodies, because they consist of the light and heavy chains, which are expressed independently and are subsequently assembled), low expression level in systemically infected leaves, and so on. ICON has solved many of these problems by designing a process that starts with an assembly of one or more viral vectors inside a plant after treating the leaves with agrobacteria, which deliver the necessary viral vector components. ICON's proviral vectors provide advantages of fast and high-yield amplification processes in a plant cell, simple and inexpensive assembly of expression cassettes *in planta*, and

full control of the process. The robustness of highly standardized protocols allows the use of inherently the same safe protocols for both laboratory-scale as well as industrial production processes. In this system, the plant is modified transiently rather than genetically and reaches the speed and yield of microbial systems while enjoying posttranslational capabilities of plant cells. De- and reconstructing of the virus adds some safety features and also increases efficiency. There is no ''physiology conflict,'' because the ''growth phase'' is separated from the ''production phase,'' so that no competition occurs for nutrients and other components required for growth and also for expression of the biopharmaceutical at the same time.

This transfection-based platform allows the production of proteins in a plant host at a cost of US$1 to 10 per gram of crude protein. The platform is essentially free from limitations (gene insert size limit, inability to express more than one gene) of current viral vector-based platforms. The expression levels reach 5 g per kilogram of fresh leaf tissue (or some 50% of total cellular protein!) in 5 to 14 days after inoculation. Since the virus process (in addition to superhigh production of its own proteins, including the protein of interest) leads to the shutoff of the other cellular protein synthesis, the amount of protein of interest in the initial extract is extremely high (Fig. 7). It thus results in reduced costs of downstream processing. Milligram quantities can be produced within two weeks, gram quantities in 4 to 6 months, and the production system is inherently scalable. A number of high-value proteins have been successfully expressed, including antibodies, antigens, interferons, hormones, and enzymes (see Klimyuk, Marillonnet, Knäblein, McCaman, Gleba (2005), books).

6.3 Simple Moss Performs Complex Glycosylation

Greenovation Biotech GmbH (Freiburg, Germany) has established an innovative production system for human proteins. The system produces pharmacologically active proteins in a bioreactor, utilizing a moss (*Physcomitrella patens*) cell culture system with unique properties (see Fig. 8). It was stated before that posttranslational modifications for some proteins are crucial to gain complete pharmacological activity. Since moss is the only known plant system that shows a high frequency of homologous recombination, this is a highly attractive tool for production strain design. By establishing stable integration of foreign genes (gene knockout and new transgene insertion) into the plant genome, it can be programmed to produce proteins with modified glycosylation patterns that are identical to animal cells. The moss is photoautotrophic and therefore only requires simple media for growth, which consist essentially of water and minerals. This reduces costs and also accounts for significantly lower infectious and contamination risks, but in addition to this, the system has some more advantages:

- The transient system allows production of quantities for a feasibility study within weeks – production of a stable expression strain takes 4 to 6 months.
- On the basis of transient expression data, the yield of stable production lines is expected to reach 30 mg L^{-1} per day. This corresponds to the yield of a typical fed-batch culture over 20 days of 600 mg L^{-1}.
- Bacterial fermentation usually requires addition of antibiotics (serving as selection marker and to avoid loss of the

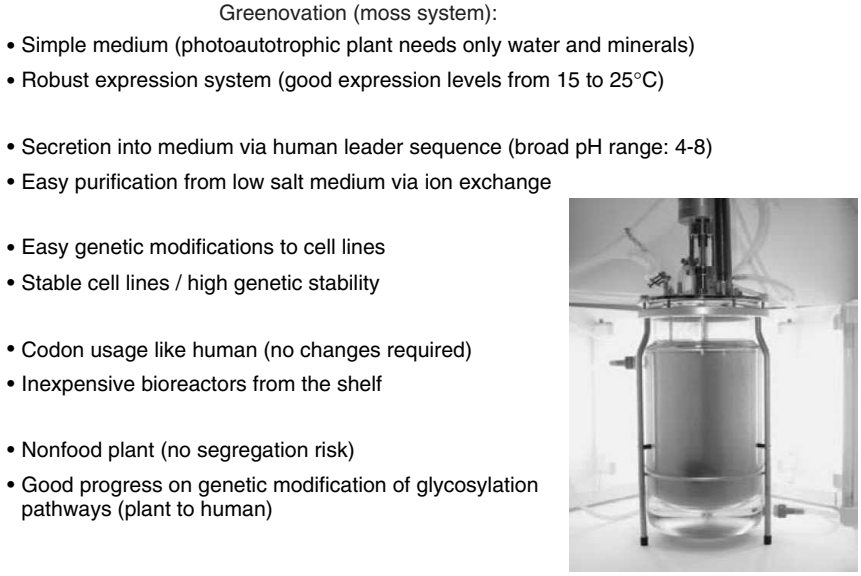

Fig. 8 Greenovation use a fully contained moss bioreactor. This company has established an innovative production system for human proteins. The system produces pharmacologically active proteins in a bioreactor, utilizing a moss (*Physcomitrella patens*) cell culture system with unique properties. Source: Knäblein J. (2003) *Biotech: A New Era in the New Millennium – Biopharmaceutic drugs Manufactured in Novel Expression Systems*, DECHEMA-Jahrestagung der Biotechnologen, Munich, Germany, 21.

expression vector). For moss cultivation, no antibiotics are needed – this avoids the risk of traces of antibiotics having a significant allergenic potential in the finished product.

- Genetic stability is provided by the fact that the moss is grown in small plant fragments and not as protoplasts or tissue cultures avoiding somaclonal variation.
- As a contained system, the moss bioreactor can be standardized and validated according to GMP standards mandatory in the pharmaceutical industry.
- Excretion into the simple medium is another major feature of the moss bioreactor, which greatly facilitates downstream processing.

As discussed in detail, the first step to get humanlike glycosylation in plants is to eliminate the plant glycosylation, for example, the attachment of β-1-2-linked xylosyl and α-1-3-linked fucosyl sugars to the protein, because these two residues have allergenic potential. Greenovation was able to knockout the relevant glycosylation enzymes xylosyl transferase and fucosyl transferase, which was confirmed by RT-PCR (reverse transcriptase PCR). And indeed, xylosyl and fucosyl residues were completely removed from the glycosylation pattern of the expressed protein as confirmed by MALDI-TOF (matrix assisted laser desorption ionization time of flight) mass spectroscopy analysis (see Fig. 9).

A very challenging protein to express is VEGF because this homodimer consists of two identical monomers linked via a disulfide bond. To produce VEGF in

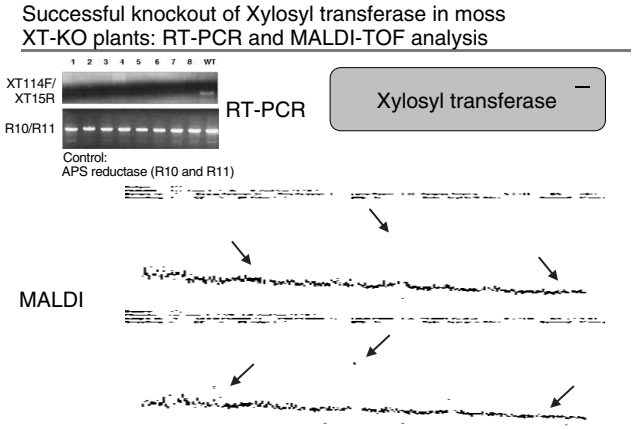

Fig. 9 Knockout of Xylosyl Transferase in moss. To avoid undesired glycosylation, greenovation knocked out the Xylosyl and Fucosyl Transferase, as confirmed by RT-PCR. MALDI-TOF results show that indeed, xylosyl- and fucosyl-residues were completely removed from the glycosylation pattern of the expressed protein (data for knockout of Fucosyl Transferase not shown). Source: Knäblein J. (2003) *Biotech: A New Era in the New Millennium – Biopharmaceutic Drugs Manufactured in Novel Expression Systems*, DECHEMA-Jahrestagung der Biotechnologen, Munich, Germany, 21.

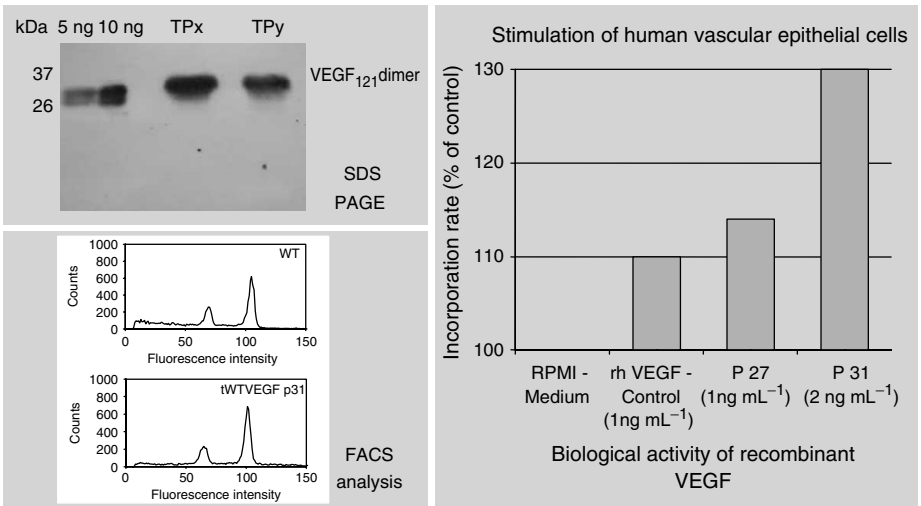

Fig. 10 Greenovation could successfully express the biopharmaceutical VEGF. This growth factor is a very complex protein consisting of two identical monomers linked via a disulfide-bond. To produce VEGF in an active form, the monomers need to be expressed to the right level, correctly folded, assembled, and linked via the disulfide-bond. The analytical assays clearly show that expression in moss yielded completely active VEGF. Source: Knäblein J. (2003) *Biotech: A New Era in the New Millennium – from Plant Fermentation to Plant Expression of Biopharmaceuticals*, PDA International Congress, Prague, Czech Republic.

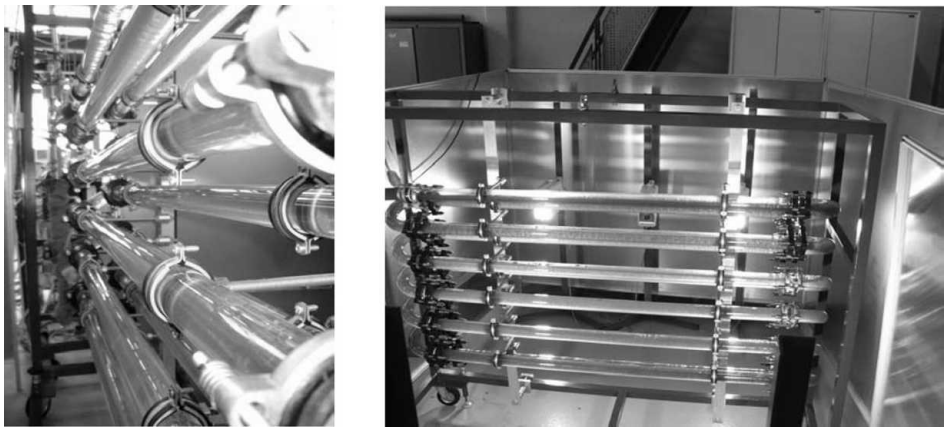

Fig. 11 Scaling of photobioreactors up to several 1000 L. The moss bioreactor is based on the cultivation of *Physcomitrella patens* in a fermenter. The moss protonema is grown under photoautotrophic conditions in a medium that consists essentially of water and minerals. Light and carbon dioxide serve as the only energy and carbon sources. Cultivation in suspension allows scaling of the photobioreactors up to several 1000 L. Adaptation of existing technology for large-scale cultivation of algae is done in cooperation with the Technical University of Karlsruhe. Source: greenovation Biotech GmbH (Freiburg, Germany) and Professor C. Posten, Technical University (Karlsruhe, Germany).

an active form, the following need to be provided:

- Monomers need to be expressed to the right level.
- Monomers need to be correctly folded.
- Homodimer needs to be correctly assembled and linked via a disulfide bond.
- Complex protein needs to be secreted in its active form.

And in fact, all this could be achieved with the transgenic moss system as shown in Fig. 10. These results are very promising because they demonstrate that this system is capable of expressing even very complex proteins. In addition to that, the moss system adds no plant-specific sugars to the protein – a major step toward humanlike glycosylation. Furthermore, moss is a robust expression system leading to high yields at 15 to 25 °C and the pH can be adjusted from 4 to 8 depending on the optimum for the protein of interest. Adapting existing technology for large-scale cultivation of algae, fermentation of moss in suspension culture allows scaling of the photobioreactors up to several 1000 L (see Fig. 11). Finally, the medium is inexpensive, since only water and minerals are sufficient.

7 Other Systems Used for Plant Expression

Several different plants have been used for the expression of proteins in plants. All these systems have certain advantages regarding edibility, growth rate, scalability, gene-to-protein time, yield, downstream processing, ease of use, and so on, which I will not discuss in further detail here. A selection of different expression systems is listed:

Alfalfa	Ethiopian mustard	Potatoes
Arabidopsis	*Lemna*	Rice
Banana	Maize	Soybean
Cauliflower	Moss	Tomatoes
Corn	Oilseeds	Wheat

Some of these systems have been used for research on the basis of their ease of transformation, well-known characterization, and ease to work with. However, they are not necessarily appropriate for commercial production. Which crop is ultimately used for full-scale commercial production will depend on a number of factors including

- time to develop an appropriate system (gene-to-protein);
- section of the plant expressing the product/possible secretion;
- cost and potential waste products from extraction;
- ''aged'' product/ease of storage;
- long-term stability of the storage tissue;
- quantities of protein needed (scale of production).

Depending on the genetic complexity and ease of manipulation, the development time to produce an appropriate transgenic plant for milligram production of the desired protein can vary from 10 to 12 months in corn as compared to only weeks in moss. Estimates for full GMP production in corn are 30 to 36 months and approximately 12 months for moss. Expression of the protein in various tissues of the plant can result in a great variation in yield. Expression in the seed can often lead to higher yields than in the leafy portion of the plant. This is another explanation for the high interest in using corn, which has a relatively high seed-to-leaf ratio. Extraction from leaf can be costly as it contains a high percentage of water, which could result in unavoidable proteolysis during the process. Proteins stored in seeds can be desiccated and remain intact for long periods of time. The purification and extraction of the protein is likely to be done by adaptations of current processes for the extraction and/or fractionation. For these reasons, it is anticipated that large-scale commercial production of recombinant proteins will involve grain and oilseed crops such as maize, rice, wheat, and soybeans. On the basis of permits for open-air test plots issued by the USDA for pharmaceutical proteins and industrial biochemicals, corn is the crop of choice for production with 73% of the permits issued. The other major crops are soybeans (12%), tobacco (10%), and rice (5%).

In general, the use of smaller plants that can be grown in greenhouses is an effective way of producing the biopharmaceuticals and alleviating concerns from environmental activist groups that the transgenic plant might be harmful to the environment (food chain, segregation risk, genetic drift, etc.).

8 Analytical Characterization

Validated bioanalytical assays are essential and have to be developed to characterize the biopharmaceuticals during the production process (e.g. in-process control) and to release the final product for use as a drug in humans. These assays are applied to determine characteristics such as purity/impurities, identity, quantity, stability, specificity, and potency of the recombinant protein during drug development. Since the very diverse functions of different proteins heavily depend on their structure, one very valuable parameter in

protein characterization is the elucidation of their three-dimensional structure. Although over the last couple of years a lot of effort was put into a method for improving the elucidation of protein structures (during my PhD thesis, I was also working in this fascinating field together with my boss Professor Robert Huber, Nobel Prize Laureate in 1988, ''for the determination of the three-dimensional structure of a photosynthetic reaction centre''), it is still very time consuming to solve the 3-D structure of larger proteins. This is why despite the high degree of information that can be obtained from the protein structure, this approach cannot be applied on a routine basis. Therefore, tremendous efforts are put into the development of other assays to guarantee that a potent biopharmaceutical drug is indeed ready for use in humans.

9 Conclusion and Outlook

The production of protein therapeutics from transgenic plants is becoming a reality. The numerous benefits offered by plants (low cost of cultivation, high biomass production, relatively fast gene-to-protein time, low capital and operating costs, excellent scalability, eukaryotic post-translational modifications, low risk of human pathogens, lack of endotoxins, as well as high protein yields) virtually guarantee that plant-derived proteins will become more and more common for therapeutic uses. Taking advantage of plant expression systems, the availability of cheap protein-based vaccines in underdeveloped countries of the world is possible in the near future. The cost of very expensive hormone therapies (erythropoietin, human growth hormone, etc.) could fall dramatically within the next decade because of the use of, for example, plant expression systems. Fears about the risks of the plant expression technology are real and well founded, but with a detailed understanding of the technology, it is possible to proactively address these safety issues and create a plant expression industry almost free of mishaps. For this purpose, the entire set up, consisting of the specific plant expression system and the protein being produced, needs to be analyzed and its potential risks assessed on a case-by-case basis. As plant-derived therapeutics begin to demonstrate widespread, tangible benefits to the population and as the plant expression industry develops a longer safety track record, public acceptance of the technology is likely to improve continuously. Plants are by far the most abundant and cost-effective renewable resource uniquely adapted to complex biochemical synthesis. The increasing cost of energy and chemical raw materials, combined with the environmental concerns associated with conventional pharmaceutical manufacturing, will make plants even more compatible in the future. With the words of Max Planck (1858–1947) ''How far advanced Man's scientific knowledge may be, when confronted with Nature's immeasurable richness and capacity for constant renewal, he will be like a marveling child and must always be prepared for new surprises,'' we will definitely discover more fascinating features of plant expression systems. But there is no need to wait: combining the advantages of some technologies that we already have in hand could lead to the ultimate plant expression system. This is what we should focus on, because, then, at the dawn of this new millennium, this would for the first time yield large-enough amounts of biopharmaceuticals to treat everybody on our planet!

Acknowledgments

I would like to thank the companies greenovation Biotech GmbH (Freiburg, Germany), ICON Genetics (Halle, Germany), and Phytomedics (Dayton, NJ, USA) for providing some data and figures to prepare this manuscript.

Keywords

Antisense RNA
Discovered as RNA that negatively controls replication initiation by hybridizing to primer RNA. Subsequently, it was found to control mRNAs particularly involved in initiator synthesis. These RNA–RNA interactions are the mechanistic basis of incompatibility in plasmids under antisense control.

Basic Replicon
Minimal sequences that allow plasmid replication characteristic of the native plasmid.

Horizontal Transfer
Horizontal (also called lateral) gene transfer is the gene exchange between individuals and may occur across species boundaries.

Incompatibility
Defined as the inability of two plasmids to be maintained in the same cell without selection. This happens if the plasmids in question have a common replication control system. Incompatibility can also arise if the two plasmid partition systems are closely related.

Iterons
Repeat sequences that bind plasmid-encoded initiator protein for replication initiation. The binding is also involved in controlling replication and causing incompatibility.

Partition
A process that ensures plasmid distribution from mother to both daughter cells.

Plasmids are extrachromosomal elements common in bacteria and archea but also found in virally transformed eukaryotic cells. The study of plasmid biology has contributed significantly to understanding regulatory principles in chromosome replication and segregation, gene targeting, gene amplification, maintenance of genome identity, and genome evolution. However, the most profound impact of plasmids on life sciences has been through their use as cloning and expression vectors. Plasmids can also have remarkably broad host range that can cross species and even kingdom boundaries. Thus, plasmids are powerful agents for gene transfer, and by the same token, they are a potential risk to human health as they often carry genes for antibiotic resistance and virulence factors. Plasmids also carry useful genes, for example, those that encode functions capable of degrading organic pollutants or fixing nitrogen. Given the prevalence of plasmids in natural bacterial isolates, undoubtedly, much remains to be discovered about the roles they play.

1 Basic Facts

Information needed for life's basic processes is present in a coded form in the DNA of chromosomes, whether the cells are bacterial, fungal, plant, or animal. But many species, bacteria in particular, contain additional DNA molecules much smaller than chromosomes, which they transmit faithfully from one generation to the next. These molecules are called *plasmids*. The term was introduced in 1952 by Joshua Lederberg as a generic term for genetic elements that can persist outside of chromosomes. Our knowledge of plasmids has come mostly from studies in bacteria, and in this article, the term ''plasmid'' will refer to extrachromosomal elements of bacterial provenance. Plasmids are not essential to their host cells but rather carry specialized information that enables the cell to cope with and survive sometimes threatening environments. Plasmids have played a crucial role in the understanding of life processes, out of proportion to their diminutive size and dispensability to the life of the cell. These features actually made plasmids attractive as research objects. Their small size made physical manipulations easy and their dispensability allowed manipulations of genes connected to vital functions such as DNA replication without worrying about consequences to the host survival. Plasmids are of interest in several disciplines. With the advent of recombinant DNA technology in the early 1970s, they have become indispensable tools for research in molecular biology. They are studied for their special features such as their being carriers of antibiotic resistance and virulence genes that have impacted profoundly the public health. The postgenomic era has kindled new interest in plasmids for their astonishing role in bacterial adaptation and diversity. Finally, plasmids are studied in their own rights to understand functions that maintain them so efficiently outside of chromosomes.

This article mainly covers the current understanding of plasmid-maintenance functions where research has been most in-depth and rewarding in terms of understanding biological regulatory principles.

2 Maintenance

DNA replication is the primary requirement for plasmid maintenance. Additionally, plasmids may have several other functional units (cassettes) that contribute to plasmid maintenance in a growing host population. Their requirement for stability becomes more critical the lower the plasmid copy number. The maintenance functions are highly controlled. Understanding the molecular basis of control has been the main goal of basic research in plasmid biology.

2.1 Replication

The basic mechanism of DNA replication is a well-conserved process and plasmids are no exception. Replication can be divided into three stages: initiation, elongation, and termination. Initiation usually occurs in conjunction with the binding of a plasmid-specified initiator protein to a locus called the origin or *ori*, resulting in the formation of a higher order structure that also involves host-encoded proteins. This leads to opening of the strands of the origin DNA duplex that allows loading of helicase for unwinding the rest of the plasmid. The synthesis of new DNA strands on the opened template strands by DNA polymerases requires a primer providing a 3′-OH end. A variety of priming mechanisms have been found from studies on bacteriophages and from the *Escherichia coli* chromosomal origin. The events subsequent to priming, elongation, and termination of replication, are remarkably similar in different replicons. Since plasmids control their replication at the stage of initiation, aspects of elongation and termination will not be discussed here.

2.1.1 Principle of Replication Control

Plasmids have defined copy numbers that can range from one to more than one hundred in a newly born cell. However, because of the stochastic nature of all biological reactions, fluctuations in copy number can arise despite stringent controls. Large fluctuations also arise in the case of plasmids like ColE1, which is believed to distribute randomly to daughter cells. If these fluctuations are not adjusted, the result is a broadening of distribution of plasmid copies per cell. This is undesirable for plasmid maintenance. Cells with too few plasmids can generate plasmid-free daughter cells. At the other extreme, cells with too many plasmids grow slowly because of the excess genetic load or because of toxicity from excessive plasmid-encoded gene products. In the absence for selection for a plasmid, these cells are likely to be outcompeted by faster growing plasmid-free cells of the population. Thus, narrowing of plasmid copy number distribution is imperative for stable plasmid maintenance. Adjusting the rate of replication does this. Instead of doubling the copy number in a cell cycle, cells with too many plasmids make fewer new copies, and the cells with too few copies overreplicate their plasmids to catch up to the desired number. This ability to make the rate of replication a decreasing function of plasmid copy number (autogenous control or negative feedback control) is the most basic requirement for plasmid maintenance. In fact, the elements that control replication have been found to be plasmid-borne without exception, signifying the importance of the function for plasmid survival. A few prototypes of

plasmid initiation control mechanisms are illustrated below.

2.1.2 Control of Primer Formation by Antisense RNA

Control of initiation is best understood for the high copy plasmid, ColE1, of *E. coli*. ColE1 copy number is about 15, meaning it is maintained at about 15 times higher than the number of *E. coli* chromosomal origin, *oriC*. (The *oriC* number increases with growth rate and so does the plasmid copy number such that the ratio of the two remains relatively constant). ColE1 has been crucial in understanding replication control for the commonly used multicopy cloning vectors such as pBR322 and pACYC184.

Replication of ColE1 type plasmids differ from many other replicons in that the ColE1 replicons do not encode any initiator protein and they depend totally on host-encoded proteins for their replication. The plasmids nevertheless code for elements that control their copy number. The mechanisms of initiation and its control have been elaborated in great detail by *in vitro* studies pioneered by J. Tomizawa at NIH. The housekeeping RNA polymerase of *E. coli* makes the preprimer RNA (RNAII) constitutively (Fig. 1). When the RNA is about 550 nucleotides (nt) long, it starts hybridizing to the template making a R-loop that could be more than 200 bp long. Normally during transcription elongation, only 10 nt of the leading edge of the RNA hybridize to the template. To form the long R-loop, RNAII must acquire specific secondary and tertiary structures, which form as RNA II is being synthesized. RNase H then digests the RNA out of the loop almost completely except for the 4 to 5 bases in the beginning of the loop (primer maturation). This residual hybrid suffices to serve as the primer for DNA polymerase I to start DNA synthesis. The switch point of RNA to DNA has been defined as the origin for this plasmid.

A shorter RNA (RNA I) about 110 nt long mediates the control of initiation. It is fully complementary to the 5′-end of RNA II and is therefore called *antisense RNA*. The hybridization of RNA I to RNA II prevents R-loop formation at the origin sequence and thereby inhibits priming of DNA synthesis. The RNA polymerase now behaves canonically and transcribes through the origin DNA as any other template without making long R-loops. It is reasonably clear that proper folding of RNAII is crucial for R-loop formation. The folding is altered upon hybridization with RNA I. In ColE1, primer maturation is rate-limiting for initiation of replication and this process is controlled by RNA I. There is an accessory regulator, Rom, that strengthens RNA I–RNA II hybridization, thereby making primer maturation less probable (Fig. 1). In the absence of Rom, the copy number increases about two/three fold.

Several general remarks on replication control can be made using the ColE1 example. Plasmids control their replication at the stage of initiation. The rate of initiation is controlled primarily by a plasmid-encoded negative regulator (RNA I). While the primer RNA acts in cis, the negative controller must be able to work in trans, and its inhibitory power must increase with plasmid copy number. (The negative element has to be able to function in trans so that the plasmid copies can communicate with each other, but the positive element can be in either cis or trans; the only requirement is that the replication frequency in the absence of inhibitor is higher than one per plasmid and cell cycle, preferably much higher.) RNA I is made

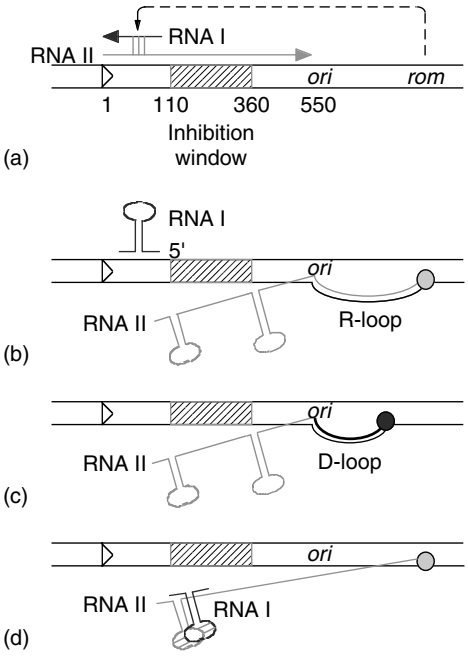

Fig. 1 Replication control in plasmid ColE1. Double-stranded DNA is shown as two parallel lines. Base pair 1 is the starting point of transcription of preprimer RNA, RNA II (gray arrow, a). For replication initiation, it is imperative that RNA II, when about 550 nt long, starts hybridizing to template strand and forms a large R-loop (b). RNase H subsequently cleaves the R-loop (not shown) and the 3′-end of the transcript is used as the primer for DNA synthesis (c). The transition point of RNA to DNA is called origin (*ori*) in this system. If RNA I (which is complementary to the 5′-terminal region of RNA II covering nt 110 to 2, leftward arrow in a) hybridizes to RNA II during the time it is being made from the inhibition window (bp 110 to 360), R-loop formation and replication initiation do not happen (d). The Rom protein helps in RNA I/RNA II hybrid formation. The schematic also shows that RNA II folding relevant to R-loop formation alters when it hybridizes to RNA I. Formation of one or more stem-loop structures is common among the regulatory RNAs in which the stem provides metabolic stability and the loop, the sequences for initial interactions with complementary RNA sequences. Other symbols: empty arrow head, promoter; gray circle, RNA polymerase; black circle, DNA polymerase.

from a constitutive promoter and is diffusible (i.e. can work in trans). As the plasmid copy number increases so does the concentration of RNA I. This in turn increases the probability of interaction with the target, the preprimer RNA. When the plasmid concentration approaches a characteristic threshold, the RNA I concentration becomes high enough to engage every preprimer RNA and prevent any further increase in plasmid copy number. Replication can resume when the RNA I concentration is reduced by dilution due to the increase in cell volume due to cell growth, and by degradation by RNases.

Efficiency of ColE1 replication control Plasmid stability improves with the rapidity with which copy number fluctuations are adjusted in a cell cycle. In an efficiently controlled system, the replication on/off switch should be tripped in response to small deviations from the steady state copy number. Ideally, replication should be negligible when plasmid concentration is high and should be frequent when plasmid concentration is lower than the steady state.

An understanding of the efficiency of control requires analysis of the dynamics of the process. It has been shown that R-loop formation can only be inhibited when the primer RNA being made is of lengths from 110 to 360 nt (Fig. 1). When the RNAII is shorter than 110 nt, it does not hybridize to RNA I. When it is longer than 360, the hybrid formation does not prevent R-loop formation, since the structure of the folded RNA relevant for R-loop formation has already been formed. This suggests that to be effective as a negative regulator, RNA I concentration has to be sufficiently high since the window of opportunity to catch the primer RNA is only the few seconds that it takes RNA polymerase to transcribe the 250-bp region. Mathematical modeling studies by Paulsson et al. have shown that the efficiency of control would be greatly improved if the 250-bp region provided multiple ($\leq$250) opportunities for hybrid formation. In the multistep mode of hybridization, the probability of replication initiation is an exponential function of RNA I concentration as opposed to a hyperbolic function in the single-step hybridization mode. The greater the number of steps, the more sensitive the replication initiation becomes to changes in RNA I concentration, and the narrower becomes the copy number distribution. For ColE1, the efficiency of control remains to be experimentally established but the available data are consistent with exponential inhibition mechanism.

In ColE1, the regulatory circuit senses copy number deviations by changes in RNA I concentration. In order to be an up to date reporter of plasmid concentration, the proportionality between RNA I and plasmid copy number needs to be maintained. If the RNA I concentration lags behind the plasmid copy number because of the delays in RNA I synthesis, the replication rate would remain high. Alternatively, elevated levels of RNA I concentration due to its finite half-life, would keep the replication rate artificially lower. Out-of-date RNA I concentrations will thus broaden plasmid copy number distribution. Thus for efficient control, constitutive synthesis of the copy number reporter (RNA I) is not enough; additionally, the regulator needs to be degraded rapidly. Counterintuitively, it is not the synthesis rate constant that determines how rapidly the RNAI concentration is increased but rather the half-life of RNAI that determines both its speed of increase and decrease.

The modeling studies also show that the rate of copy number adjustments is higher with increased transcription of RNA II. The steady state plasmid copy number (average copy number during logarithmic phase of host growth) also depends on the rate of primer RNA synthesis (the plasmid copy number increases if the primer promoter strength is increased). Thus, the three contributors to the efficiency of control are the mechanism of inhibition (hyperbolic vs exponential), high degradation rate of RNA I, and high initiation rate of RNA II. The latter (a positive function) plays as important a role in control as the negative regulator (RNA I). Plasmids are said to be under negative control because without a negative regulator, continued increase in plasmid copy number cannot be checked, which is lethal to the host (runaway replication). However, when subjected to rigorous mathematical modeling, the ColE1 example teaches us that both the steady state copy number and the rapidity with which adjustments are made to deviations from steady state copy number, are the result of both positive and negative activities. Adjusting the strength of either activity can alter the steady state and adjustment rate values.

Stable maintenance demands correction of fluctuations in either direction. In both up- and down-fluctuations, a high transcription rate of RNA II and repression by RNAI are required. In other words, although necessary, negative control is not sufficient for efficient replication control.

2.1.3 Control of Initiator Synthesis by Antisense RNA

In several plasmids, the copy number is determined by the availability of initiator proteins (i.e. initiators are rate-limiting for replication). In all these cases, the primary control element for initiator synthesis is an antisense RNA. The interaction of the antisense RNA with its target RNA inhibits initiator synthesis. Some better-studied examples are discussed below.

A straightforward mechanism is in the case of high copy streptococcal plasmid pMV158 (copy number about 20). The antisense RNA directly interacts with the translation initiation signals (ribosome binding site or RBS) of the RepB initiator mRNA and thereby downregulates its translation (Fig. 2a). The RepB–mRNA level itself is also regulated by a transcriptional repressor (CopG), a second control element for the plasmid initiator. The antisense RNA is stronger of the two control elements as it exerts stronger incompatibility (see Sect. 2.5)

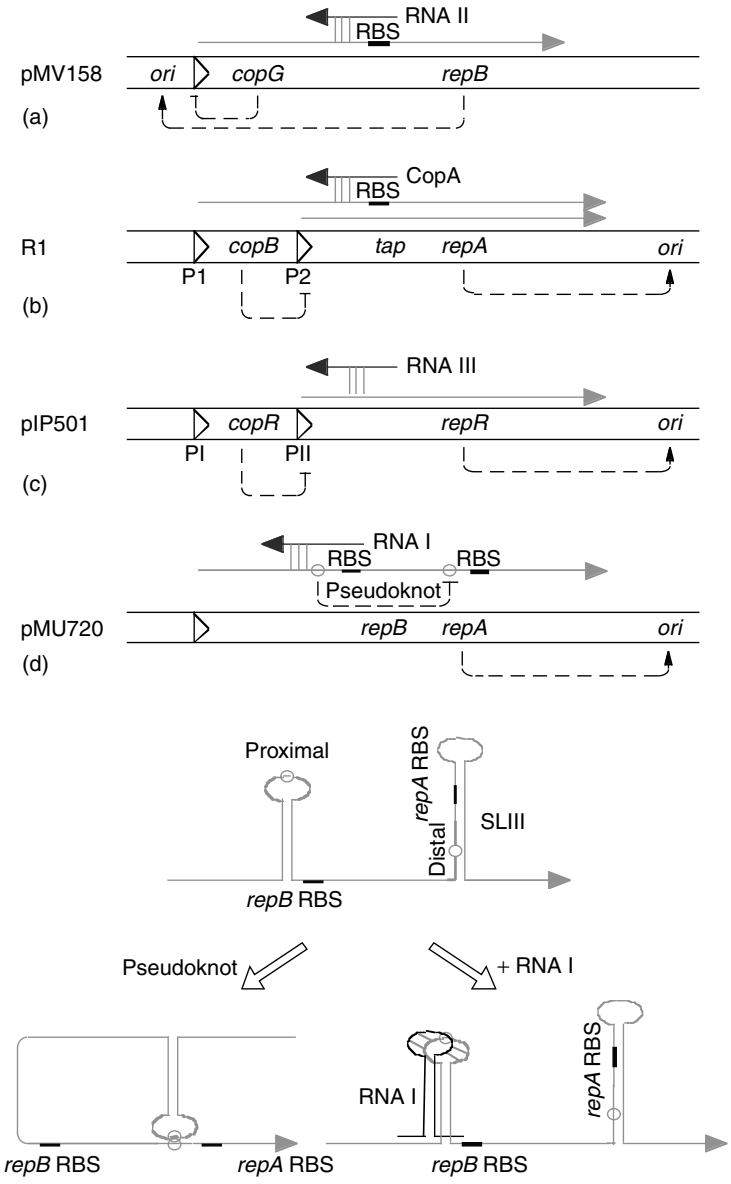
In plasmid R1, a low copy enterobacterial plasmid, the initiator (RepA) translation is regulated indirectly by the antisense RNA (CopA) (Fig. 2b). RepA can be synthesized from either of the two transcripts, the longer of which also encodes the CopB protein. CopB represses the promoter for the shorter transcript (P2), making the constitutively made longer transcript practically the only source of RepA. The CopA antisense RNA binds to a homologous region of RepA mRNA. The binding inhibits translation of an adjacent small gene called *tap*. The translation of *tap* is required to break a stable RNA secondary structure that blocks the RBS of *repA*. The translation of *repA* is therefore coupled to that of *tapA*. Thus, CopA regulates *repA* translation indirectly through TapA.

When R1 copy number becomes exceptionally low, CopB level also drops releasing repression of P2, the stronger of the two promoters that can synthesize RepA. The resulting stimulation of initiator synthesis quickly increases R1 copy number until CopB repression is reestablished and the copy number returns to the steady state level. The increased P2 activity also increases RepA synthesis by interfering with *copA* expression (convergent

Fig. 2 Mechanisms for limiting replication initiator proteins for controlling plasmid copy number. The primary control element in these plasmids is also an antisense RNA. Hybridization of antisense RNA with complimentary sense RNA sequesters the translation initiation signal (RBS) of the initiator itself (a) or an activator of initiator translation (tap in b, RepB in d). The hybridization can also prevent initiator transcription by prematurely terminating the initiator mRNA (c). All these plasmids also have a protein that negatively regulates initiator transcription (a–c) or initiator translation (d). The regulators sometimes function in more than one way. For example, when CopB level is down, derepression of the P2 promoter of R1 not only increases *repA* mRNA but also helps in initiator synthesis by interfering with (convergent) antisense transcription. In pMU720, the antisense RNA (RNA I) prevents simultaneously translational activation of *repA* through RepB and pseudoknot formation. The complementary sequences for pseudoknot formation are shown in thick gray lines with an empty circle. Other symbols are as in Fig.1.

transcription) to some extent. Thus, CopB is there primarily to boost copy number if it becomes abnormally low and thereby avoid plasmid loss, but normally CopA suffices to adjust for fluctuations in copy number during steady state growth.

In IP501, a streptococcal plasmid whose genetic organization is similar to that of R1/pMV158 involving two negative regulators, the antisense RNA limits initiators by transcriptional rather than translational control. CopR represses the pII



promoter, the only promoter for the initiator, RepR (Fig. 2c). The basal level of pII activity is high enough to maintain the plasmid. During transcription elongation, the *repR*–mRNA can adopt two mutually exclusive conformations depending on whether the antisense RNA is present or not. The binding of the antisense RNA leads to the formation of a transcriptional terminator (attenuator) that aborts transcription before the full-length *repR*–mRNA is made. Transcription attenuation is well known in many biosynthetic operons but the modulating translation elongation in the leader region of the message generates the transcription terminator.

In a group of plasmids (pMU270/pCol-IB-P9) unrelated to R1, the replication control region is similarly organized but the *rep* translation additionally requires activation by formation of a RNA pseudoknot (a tertiary motif in which nucleotides from the loop region of a stem-loop pair with a single-stranded distal region). In pMU270, the *repA* translation is coupled to that of a leader peptide (RepB) as in plasmid R1 (Fig. 2d). The translation of *repB* disrupts a stable stem-loop structure (SLIII) that otherwise sequesters the distal pseudoknot sequences, and the RBS and translation start codon of *repA*. Unlike R1, in these plasmids, the translation coupling is not enough: *repA* translation further requires activation by the formation of a pseudoknot immediately upstream of the *repA* RBS. A small antisense RNA, RNA I, controls replication by inhibiting translation of repB and thereby translation coupling, and by preempting pseudoknot formation by sequestering the proximal pseudoknot bases.

In pT181 family of plasmids also, the antisense RNA controls initiator (RepC) availability by transcriptional attenuation (Fig. 3). An additional but completely novel mechanism operates to limit RepC availability further. At the termination of one round of replication, the initiator is inactivated, preventing its recycling. The plasmid pT181serves as a classic plasmid example in which replication starts by the rolling circle mechanism i.e. by nicking the plus strand of the double-strand origin (called DSO, Fig. 3) by one of the subunits of RepC dimer. The inactivation is associated with a second nicking at DSO at the termination of replication. For reasons not clear yet, replication continues beyond one round by about 10 nt and then stops. This regenerates the DSO, which is cleaved by the unused subunit of the RepC dimer. This initiates a concerted strand transfer cascade, generating a single-stranded (SS) monomer corresponding to the displaced plus strand, and release of the initiator protein as an inactive heterodimer with one subunit of RepC dimer covalently linked to an oligonucleotide corresponding to about 10 nucleotides immediately 3′ to the nick site. The heterodimer RepC/C* is inactive in nicking and in initiation of replication. The replication cycle therefore involves two nickings, one at initiation and one at termination, and two closings, one for the new and one for the old leading strand, justifying why RepC needs to be a dimer. In other plasmids (pC194, pUB110), although the nicking-closing activities reside on a monomer, it has two separate active sites.

Replication kinetics in R1 and pT181 The kinetics of copy number control has been experimentally analyzed in plasmid R1. The rate-limiting step, also the case in ColE1, is the initial complex formation between the sense and antisense RNAs. The antisense RNA is unstable

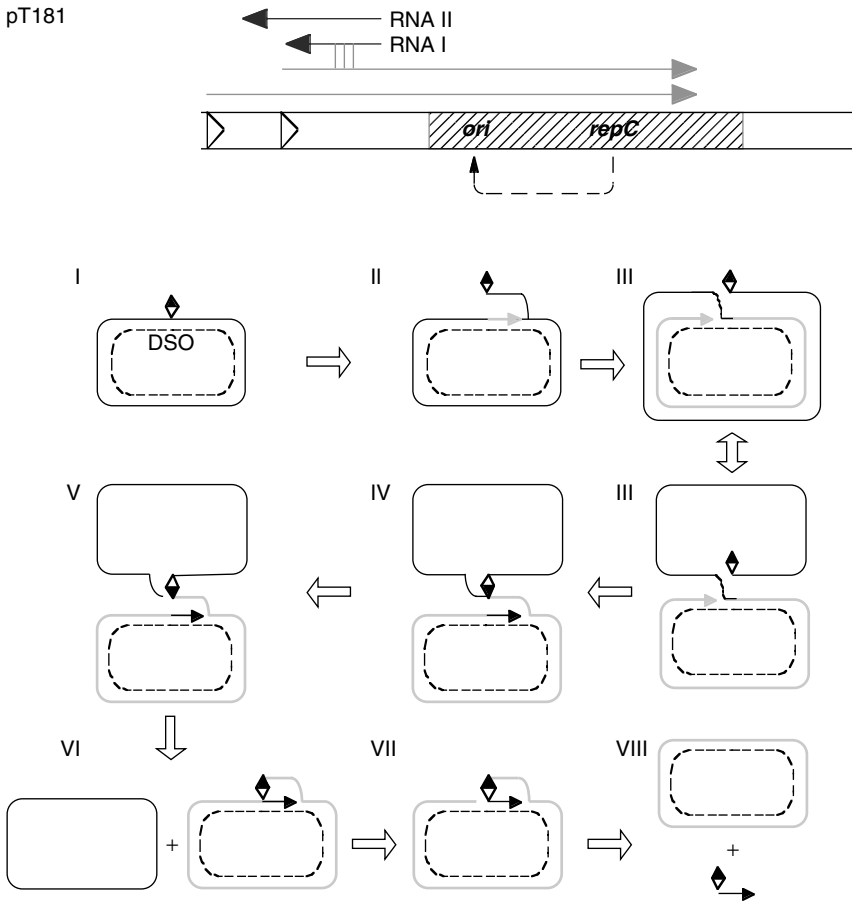


Fig. 3 Steps in pT181 replication with inactivation of initiator protein RepC at the termination of replication. The replicon is shown at the top. One subunit of a RepC dimer (black and white diamond) makes a nick at the origin (DSO) on the plus strand (I) and gets covalently attached to the 5′ end. The free 3′-OH end is then extended by new synthesis (gray line with arrowhead showing the growing end, II). At the end of one round of synthesis (III), the replication continues beyond the nick site a short distance (bold arrow, IV). The second subunit of the dimer initiates a concerted strand-transfer reaction by nicking the newly synthesized origin (V). The newly generated 3′OH end then attacks the old RepC–DNA bond releasing RepC and restoring the continuity of the old plus strand, which is then released as a single-stranded circle (VI). The free RepC subunit (white triangle of the diamond) then attacks the nick site generated on the newly synthesized strand. Finally, the 3′OH end generated by the nicking (VII) attacks the DNA–RepC bond generated in step V. The end products of this reaction are a double-stranded plasmid molecule with one newly synthesized strand, and a RepC/C* heterodimer with the covalently bound short oligonucleotide (about 12mer) to one of the subunits (VIII). The heterodimer is inactive as an initiator.

($t_{1/2} = 1–2$ min), and therefore its concentration can be taken to sense plasmid concentration. As in ColE1, the key parameter in determining the initiation rate is the concentration of antisense RNA but the inhibition kinetics is hyperbolic (e.g. replication initiation frequency decreases twofold if the copy number increases twofold). This will lead to a gradual restoration of copy number to the steady state value. The relatively slower rate of correction (compared to the exponential inhibition mechanism proposed for ColE1) apparently has not been a problem because of other maintenance functions, particularly, the CopB-mediated boosting of initiation rates when the copy number drops abnormally.

Replication kinetics studies in the case of a multicopy plasmid, pT181, have been particularly telling on how the copy number approaches the steady state value from low copy situations (termed repopulation). The lowering of copy number was achieved using a *repC*(ts) mutant plasmid at the nonpermissive temperature. Upon return to the permissive temperature, copy number increased rapidly and went beyond the steady state value before replication was inhibited. The copy number then returned to the steady state value gradually. The repopulation kinetics was similar when a plasmid copy was introduced to a plasmid-free cell. In the low copy state, when the inhibitor concentration was correspondingly low, replication rate was maximal that brought the copy number up to and beyond the steady state value rapidly. The overshoot in copy number is expected because inhibitor accumulation lags behind copy number increase. However, when sufficient inhibitor accumulates, negative control becomes the overriding force that prevents continued increase in plasmid copy number.

Although the instability of antisense RNA has been argued to be important for rapid copy number correction, an exception has been found in plasmid pIP501 (Fig. 2c). The antisense RNA in pIP501 is quite stable ($t_{1/2}$ = about 30 min as opposed to about 1–2 min in other cases) but the copy number correction is apparently not sluggish enough to cause significant plasmid instability. The Cop repressor of the plasmid is made constitutively (like R1). A reduction in copy number may therefore lead to derepression of the Rep promoter and increased initiator synthesis that would help bring the copy number back to the steady state level. The binding of Cop repressor to its operator in pIP501 is weaker compared to the situation in R1, and this may allow easier depression of initiator synthesis and prevent undershoot of copy number that is expected from a stable (''out-of-date'') reporter of plasmid copy number. Cop of pIP501 is also stable ($t_{1/2} = 40$ min, comparable to the generation time). With both the negative regulators being stable, this plasmid should have a relatively broad copy number distribution in a population of cells.

2.1.4 Control of Initiator Synthesis by Iterons

Antisense RNA is not the only negative regulator known to control plasmid copy number. There is a separate group of plasmids (prominent members include F, RK2, R6K, P1, pSC101, and pSL10) in which the negative regulators are short (20 bp or so) repeated sequences, called *iterons*. The hallmark of this group of plasmids is the presence of five or so iterons in the origin of replication. Iterons are essential for initiation and therefore they serve dual function of both effecting

initiation and controlling negatively the initiation frequency. As the iteron concentration increases with increases in plasmid copy number, the negative regulatory activity of the iterons becomes the overriding feature that apparently turns off replication altogether when the copy number becomes excessive.

The known activities of iterons are that they bind plasmid-encoded replication initiator protein Rep, and they pair via the bound Rep. The Rep protein concentration is usually controlled by transcriptional autoregulation and posttranslationally by the formation of inactive dimers. The *rep* promoter region is either found buried within the iterons in the origin or has overlapping inverted half-iterons (dyads). Rep binds to iterons as monomer and to the dyad as dimers and shuts off the promoter activity efficiently. Thus, Rep autoregulates its own synthesis. Although the monomers serve as initiators, the protein is found largely as dimer, which are inactive in iteron binding and hence cannot serve as initiators. The transcriptional autorepression and dimerization are the two known mechanisms that can limit active initiator availability. In the presence of some of the molecular chaperones (DnaJ, DnaK, GrpE, ClpA, and ClpB), the inactive Rep is converted to the active monomeric form. The chaperones thus contribute positively to the initiator pool. An alternate mechanism of activation is interaction with iteron DNA itself (DNA induces conformation change in Rep that dissociates dimers into active form). The primary mechanism to prevent plasmid overreplication is currently believed to be pairing of iterons by bound Rep (dubbed ''handcuffing''). These multitudes of controls involving the initiator apparently maintain the plasmid copy number within narrow limits. Rep proteins have domains in common with replication initiators encoded by organisms in all three kingdoms of life, making their detailed study into one of general importance.

The current view of the replication cycle based primarily on results of P1 is as follows (Fig. 4). The replication initiates when origin iterons are saturated with Rep. The binding is most likely cooperative, best shown in the case of R6K. The act of replication elongation frees the *rep* promoter of bound Rep and provides a window of opportunity for maximal *rep* transcription (''replication-induced transcription''). The newly formed Rep is inactive and forms dimer. Thus, although Rep synthesis maximizes immediately after an initiation event, this does not encourage another round of replication right away. If this were the case, runaway replication would follow. Thus, Rep inactivation by dimerization appears obligatory to prevent uncontrolled overreplication. The preexisting active Rep most likely gets distributed to daughter origins (titration) so that none can be saturated and this can aid to prevent premature initiation also. The origins can pair by the bound Rep and this is believed to cause steric hindrance to origin function. It is generally accepted that formation of a higher order nucleoprotein complex activates an origin, and it is reasonable to assume that handcuffing will be on the way to the formation of such a complex. As active Rep accumulates by the mediation of chaperones, the origins can saturate again. Our best guess is that intramolecular cooperative interactions among bound Rep molecules, Rep interactions with host factors (DnaA, DnaB, and DnaG), and the presence of architectural proteins like IHF or HU all cooperate to form a complex that reverses the handcuffing and makes initiation possible again.

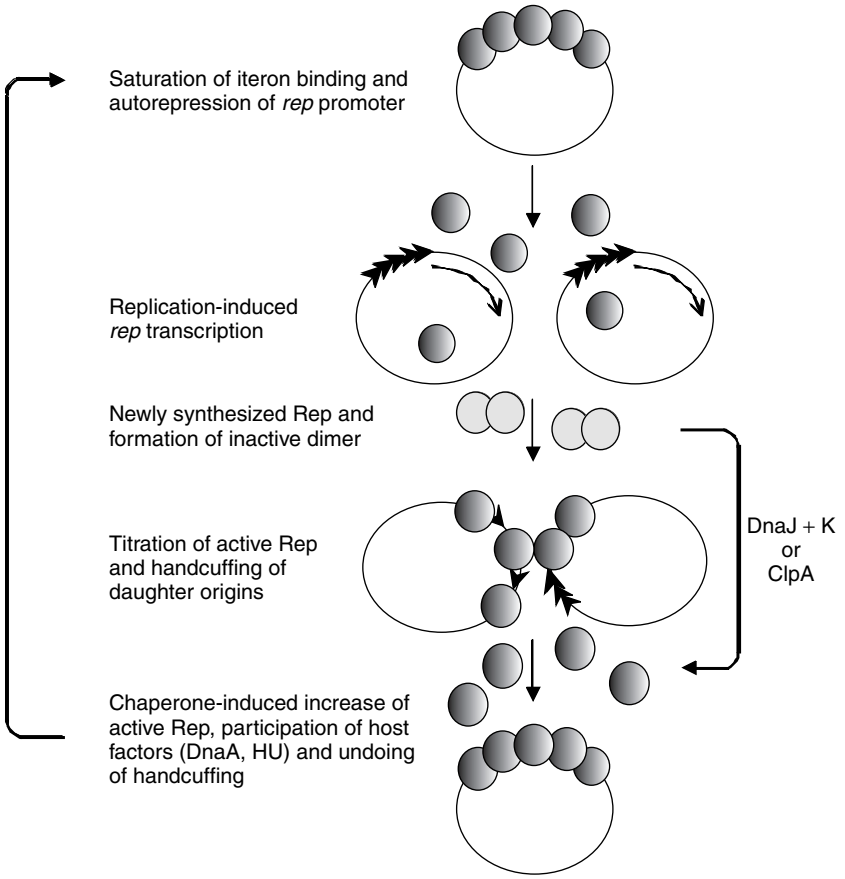

Fig. 4 A model on how Rep protein controls replication of an iteron-carrying plasmid, P1. Rep protein (gray sphere) binds to five repeated sites (iterons) in the origin that simultaneously achieves initiation as well as autorepression (the iterons also serve as operators of *rep* transcription). When the replication fork traverses the iterons (black arrow heads), the promoter is cleaned of bound Rep, promoting a burst of *rep* transcription (replication-induced transcription; bent arrows, *rep* transcription). However, the newly made Rep misfolds (light gray spheres) that encourages dimerization. Rep dimers are defective in iteron binding and require chaperones (DnaJ and DnaK or ClpA) for activity. The active Rep is titrated by the daughter origins that also allow pairing of origins by Rep–Rep interactions (handcuffing). Handcuffing is believed to be an impediment to initiation and must reverse to allow the next round of replication. Increase in Rep activity and participation of other host-encoded initiators apparently make the origin initiation-competent again and the cycle continues.

Iteron mediated control is very precise as it can maintain plasmids faithfully as low as one in a newborn cell. How the precision is achieved is not known but the presence of multiple iterons, and multiple modes of control on Rep synthesis and activity (cooperative binding, autoregulation, inactivation by dimer formation, activation by chaperones, titration and handcuffing, and interactions with multiple host

factors) are there to avoid fluctuations that otherwise would be inherent in a low frequency event.

2.2 Partition

Other than precise duplication of the genome, chromosome maintenance in all organisms involves equal distribution of DNA copies (sister chromatids) to daughter cells (mitosis). A mitosis-like partition system, called *par*, also functions for maintenance of low copy number plasmids such as F, P1, and R1. Plasmids differ from chromosomes in that plasmid copies are identical to each other whereas in mitosis only sister chromatids are identical. Unlike mitosis, there is no obligatory need for plasmids to be equipartitioned. In principle, plasmid maintenance can be assured even if each daughter receives just one plasmid copy. An efficient replication control system can then bring the copy number to the steady state value rapidly. Experimental evidence in this regard is rather meager and thus in support of the equipartition model.

Plasmids like ColE1 do not encode a *par* system. Nonetheless, the plasmids are maintained stably because of their high copy number. Since the probability that a plasmid will not enter a particular daughter is 0.5, and if there are $2N$ plasmid copies in a dividing cell (N being the copy number in a new born cell), the probability that none ends up in that daughter is $(0.5)^{2N}$, which is the expected loss frequency per cell per generation. For a plasmid like pBR322 in which $2N$ can be 40, the loss frequency is expected to be about 10^{-12}, whereas for plasmids like P1 and F, where $2N$ can be 2, the loss frequency can be as high as one out of four cells. These loss rates make it obvious why high copy number plasmids do not have *par* and vice versa.

2.2.1 Regulation of *par*

The *par* genes exist as a cassette and are remarkably uniform in terms of their genetic organization. In all cases, they encode two trans-acting proteins, usually called ParA and ParB, and one cis-acting region called *parS* (*S* for site), the centromere analog (Fig. 5). The genes for ParA and ParB are in an operon that is autoregulated. ParA is an ATPase and ParB binds *parS*. However, the ATPase can be of two types and on this criterion, plasmids have been classified as type I with Walker-type ATPase (as in P1 and F), and type II with actin-type ATPase (as in R1). The type I plasmids have been further separated into two types depending upon whether the operator/promoter region for autoregulation is a separate locus (type Ia) or coincides with the *parS* site (type Ib). The autoregulatory site of type II plasmids also coincides with *parS* as in type Ib. The regulation of the *par* operon is known in detail in several plasmids. It is particularly intriguing in type Ia plasmids in which ParA serves as the repressor primarily when in the ADP-bound form in those plasmids in which the two forms have been distinguished. ParB and *parS* serve as corepressors and significantly improves the repressive effects of ParA.

The tight regulation of *par* suggests that the levels of the components are critical for function. In fact, overproduction of any of the three components in trans destabilizes plasmids, that is, causes partition-mediated incompatibility (see Sect. 2.5). The mechanisms of destabilization are largely unknown but likely to vary depending upon the destabilizing (incompatibility exerting) component. The incompatibility due to *parS* could be either

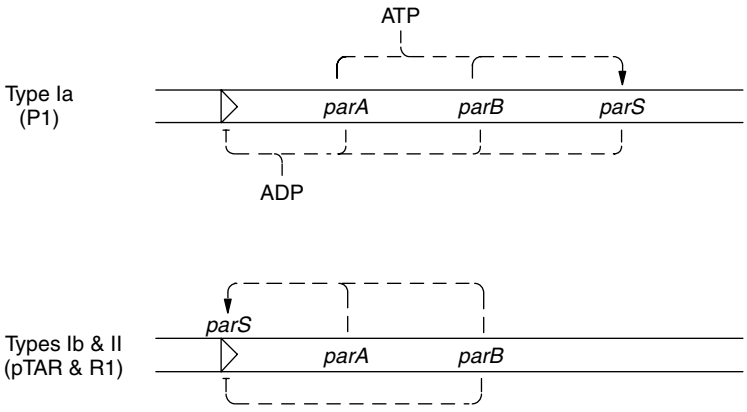

Fig. 5 Genetic organization of *par* operons. The operons consist of genes for two trans-acting proteins, ParA and ParB, and a cis-acting site, *parS*, which serves the function analogous to a centromere. The operons have been classified according to whether the ATPase domain of ParA is Walkerlike (type I) or actinlike (type II), and whether the promoter and *parS* are separate (type Ia) or overlapping (type Ib and II). The operons are autoregulated in all cases, sometimes, involving all three components as in plasmid P1. The ATP form of ParA is involved in partition whereas the ADP form is used in autorepression.

due to titration of an essential plasmid or host component for partition. A more attractive possibility is that the cloned *parS* pairs with a target (incompatibility sensitive) plasmid thereby precludes its pairing with its sister, believed to be an essential early step in partition. In P1 and F, the mechanism of destabilization by excess ParB is likely to be spreading of ParB on DNA and silencing of genes on its wake (see Sect. 2.2.3). ParA could be exerting incompatibility by breaking plasmid pairs.

2.2.2 **Partition Dynamics**

Our understanding of the dynamics of partition process owes greatly to recent technological developments that allow mapping of proteins and DNA sites within cells by fluorescence microscopy. Both the proteins and the sites can be directly tagged with green fluorescence protein (GFP) or its derivatives, and visualized in live cells in real time. Alternatively, mapping can also be done using immunofluorescence microscopy that does not require tagging *in vivo*, but this can only be done in dead cells. On the basis of their results on R1, Gerdes and colleagues have provided a model for plasmid partition for the type II (actin-type) *par* cassette. Following plasmid replication in the midcell, the sister plasmid copies pair via ParR (ParB analog) bound to *parS*. The pairing process also requires ParM (ParA analog) bound to ATP. The pairing apparently provides a signal to ParM to start forming a linear polymer that pushes the sister plasmids away from each other towards the cell pole. On reaching the polar location, the sisters stay anchored till the cell division is completed. The situation is analogous to mitosis in that the plasmids first pair at the centromere and are then pulled or pushed apart to opposite halves of the cell. Several recent findings, not necessarily from R1 alone, fit with the above model. The replication factory is

stationed in the midcell and plasmids are incorporated in the midcell for replication. In smaller cells, plasmids are found in midcell and in longer cells either in cell quarters (future midcells as in P1 and F) or in more polar positions (as in R1). Simultaneous mapping of several plasmids has indicated that plasmids have discreet nonoverlapping locations. The ParM (ParA analog of R1) forms filaments that can span the entire cell length. This requires an intact ATPase domain of ParA and other two *par* components, ParR and *parS*. The genetic requirements for filament formation and partition are thus identical, implying that the former is important for the latter.

The filament formation has explained how plasmids can move apart at speeds that are an order of magnitude faster than the cell elongation rate. Previously, attachment to cell membrane and movement in sync with membrane growth was the proposed mechanism of moving daughter chromosomes/plasmids apart. This mode of movement is too slow to account for the observed speed of plasmid movement. Hitchhiking on the chromosome instead of membrane was another possibility, but this is unlikely since plasmids can segregate to chromosome-less (anucleate) cells. ParA filaments may help in an alternate way by providing tracks on which plasmids can be transported, as is the situation in mitosis where molecular motors carry chromosomes along the microtubules tracks. It is not known whether the ATPases of type I plasmids also form filaments or whether they provide the energy of movement in some other way. Determination of the details of plasmid movement remains the most challenging aspect of understanding the partition problem.

It is also not known how the plasmids stay in their polar destination after they reach there, and how they are recruited for replication. To date, no host genes involved in plasmid partition have been identified. Some of the genes implicated in partition of bacterial chromosomes (e.g. *mukB, smc*), apparently, do not contribute to plasmid partition. This is not surprising considering the additional complexity of partitioning a much larger size element such as a chromosome. In fact, chromosomal *par* genes so far identified all seem to be involved in condensing the nucleoid. Compaction afforded by negative superhelicity may suffice for plasmids and additional mechanisms are called for only when the chromosome size gets unwieldy.

2.2.3 Unexpected Aspects

Binding of SopB of F and its analog ParB of P1 to their centromeric sites (*sopC/parS*) can silence surrounding gene expression over several kilobases. The silenced region has also been shown to be inaccessible to DNA gyrase and DNA adenine methylase. Such long-range effects on DNA for sequence-specific DNA-binding proteins are surprising since transcriptional repressors only control expression in an operon-specific way. ParB type proteins also serve as classical repressors as they participate in autoregulation of *par* operons. ParB homologs are also known to act as transcriptional factors sometimes without playing any role in partition (e.g. VirB protein of *Shigella* virulence plasmid). But only binding to the centromeric sites seem to mediate silencing so far.

The silencing is likely to be due to spreading of ParB bidirectionally on DNA from the *parS* site by nonspecific binding. DNA covered with ParB apparently precludes other DNA–protein interactions.

An alternative model is that ParB concentrates on subcellular compartments forming a patch that attracts *parS* and sequesters adjoining DNA by nonspecific binding. The nonspecific binding is expected to follow because of high local concentration of ParB in the patch (homing site). The relevance of silencing to partition is not obvious, but the latter model is easier to appreciate because it can bring a *parS*-containing plasmid to subcellular location and thereby help in their segregation. In eukaryotes, centromeres are associated with heterochromatin and are transcriptionally silent. In fission, yeast heterochromatin proteins serve a critical role in chromosome segregation as they are required to load components of mitosis such as cohesin. In budding yeast, unstable plasmids lacking a centromere can be stabilized efficiently by transcriptionally silent mating-type locus or telomeric repeats. These spindle-independent segregation mechanisms require proteins that are also required for silencing. One such protein, Sir4p, apparently tethers plasmid DNA to an immobile nuclear component that divides between progeny at mitosis. These links of gene silencing with chromosome segregation may indicate that silencing is important in partition of bacterial plasmids.

ParA (of plasmid pB171) has shown another novel phenotype – it oscillates between the two cell extremes with a periodicity about one fifth of cell generation time. The oscillation requires the ATPase activity and other two components of *par*, ParB, and *parS*. Two other proteins related to ParA by virtue of having Walker-type ATPase motif, Soj of *Bacillus subtilis*, and MinD of *E. coli* also can oscillate requiring other related components. MinD oscillation helps to define the midcell (cell division plane) but how the oscillation could help plasmid segregation is unclear. The requirements for ParA movement and plasmid partition being identical suggest that the former is important for the latter.

Fluorescence microscopy has revealed that plasmids stay in clusters but there is no clue yet as to how they do so. Clustering should be problematic for stability of plasmids lacking *par*, as the number of segregation units will be greatly reduced. In spite of clustering, the stability measurements indicate as if the plasmids diffuse freely, independent of each other. A conceptual solution to this paradox has been proposed. The idea is that replication can decluster plasmids and make them segregate as free copies that follow replication. The Austin group has presented a dynamic view of clustering and declustering for plasmid P1 and this could lead to a radically different view of partition. Plasmid copies are found first to coalesce at midcell. At the time of cell division, the cluster splits and plasmid copies are ejected away from each other. This way, one or more plasmid copies are segregated to each half of the dividing cell. The placement of the plasmid cluster at the cell division plane makes the completion of cell division contingent upon clearing the plane of plasmids that may otherwise cause steric hindrance. The model is attractive for its inherent checkpoint control feature.

2.3 Postsegregational Killing

Postsegregational killing (PSK) systems are widespread among plasmids and also in chromosomes of bacteria and archea indicating their importance in the prokaryotic world. The PSK systems usually

consist of a two-gene (bicistronic) operon that stabilizes plasmids by a different mechanism from that of partition. One gene codes for a stable toxin and the second a relatively unstable antidote that neutralizes the effect of the toxin. As long as a plasmid is present in a cell, the regulation of the operon is such that the antidote dominates over the toxin and there is no undesirable effect on the cell. In case the plasmid is lost, the relatively stable toxin is retained longer than the antidote and causes growth arrest or even death of the plasmid-free cell. The toxin effect is restricted to plasmid-free cells only, and their selective loss increases the fraction of plasmid-carrying cells in the population. The plasmid therefore appears more stable (PSK does not reduce the frequency of appearance of plasmid-free cells). Once a cell has acquired a plasmid with the PSK system, it essentially cannot survive without it. For this reason, the PSK system has also been called a *plasmid addiction* system or, since these operons also exist in genetic elements other than plasmids, a *genetic addiction* system. The killing of plasmid-free cells is quite analogous to programmed cell death or apoptosis (a Greek word meaning ''falling off'') in multicellular eukaryotes.

Note that the killing by the addiction system is from within. There are also plasmids like ColE1 that can increase plasmid stability by killing plasmid-free neighboring cells from without. ColE1 produces a bacteriocidal agent called *colicin*, which does not harm the plasmid-carrying cells because the plasmid also carries an immunity gene, but the secreted colicin can kill plasmid-free cells in the immediate environment, thereby conferring a competitive growth advantage to the plasmid-carrying cells.

2.3.1 Classification and Regulation of Addiction Systems

The antidote prevents toxin action either by direct protein–protein interactions as in proteic systems, or by preventing toxin translation as in antisense-regulated systems, or by modifying the target of the toxin as in restriction–modification systems. A classic example of a proteic system is the Ccd (control of cell death) system encoded in the *ccdAB* operon of plasmid F. CcdB is the toxin and its expression in the absence of the antidote protein, CcdA, causes induction of the SOS pathway, which entails cell filamentation and ultimately cell death. In plasmid-free bacterial segregants, CcdA is degraded by Lon protease but CcdB persists, converting DNA gyrase to an endonuclease. DNA gyrase is an enzyme that is essential for DNA supercoiling and cell viability. CcdB traps an intermediate of the supercoiling reaction in which the gyrase is covalently bound to cleaved strands of DNA. The double-strand break can cause cell filamentation by inducing SOS response, which is known to be a biological response to DNA damaging agents. However, it is not known whether the death is due to poisoned gyrase that only cleaves DNA or due to loss of DNA supercoiling or both. CcdB can also stabilize the cleaved DNA–gyrase complex and these complexes can serve as roadblocks for elongating RNA polymerases. This can be an additional mechanism contributing to cell death. Interestingly, the antidote CcdA can reverse the cleaved complex and restore DNA integrity, as well as remove the roadblock to transcription, by sequestering CcdB as a tight CcdA–CcdB complex that also frees gyrase from DNA. Most likely, in plasmid-carrying cells, there are not sufficient free CcdB to cause any harm to the cell but the capability to reverse damage ensures survival of

plasmid-carrying cells, should the amount of CcdB transiently rise to toxic levels.

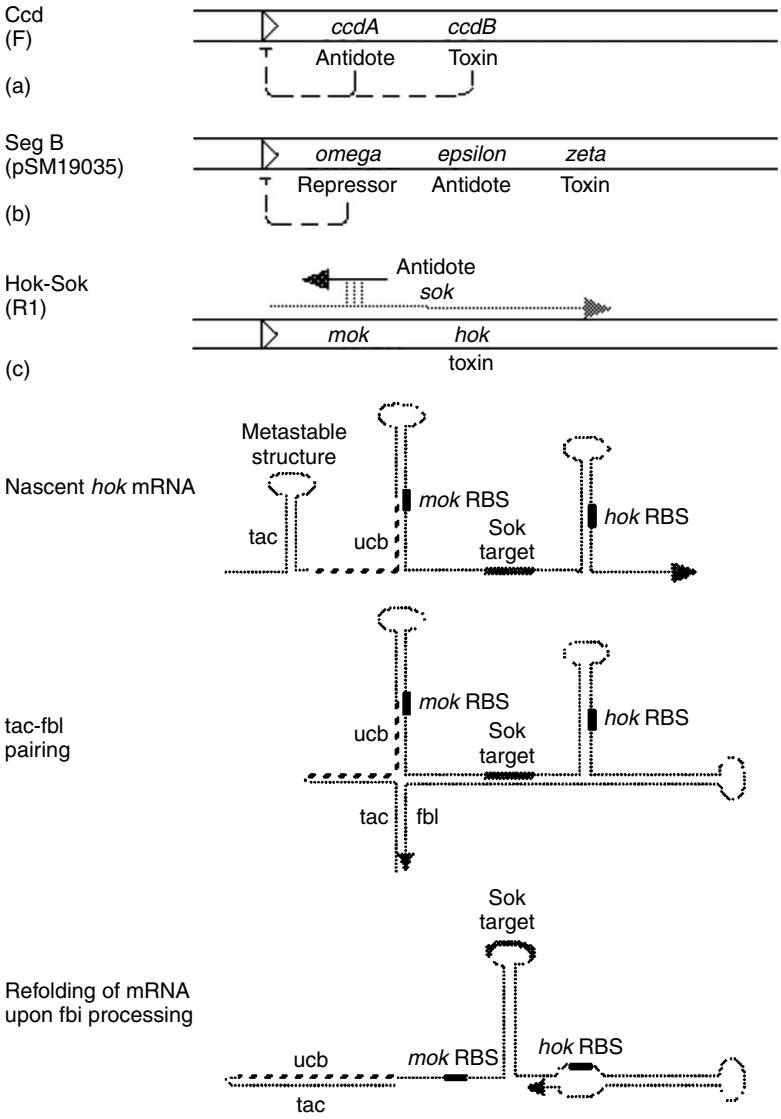
Expression of the addiction operons is regulated efficiently. This is expected since the relative levels of the two gene products are critical for cell survival. A common mechanism in proteic systems is autoregulation in which the antidote acts as a transcriptional repressor by binding to the operator–promoter region of the operon (Fig. 6). In many cases, the toxin acts as a corepressor and greatly improves repression (e.g. in *ccd* of F and *phd–doc* of plasmid P1). Moreover, the ratio of the two proteins is important for DNA binding. In the case of *ccd,* the binding is efficient with a CcdA:CcdB ratio of one. Excess of CcdA still maintains repression but derepression occurs when CcdB is in excess of CcdA. This way, the harmful effect of CcdB can be prevented in plasmid-carrying cells but there will be enough of it to cause harm in plasmid-free cells. The autoregulation is less complex in some other systems that have a three-protein operon and the extra protein solely serves as the autoregulator of transcription (e.g. Omega in SegB region of plasmid pSM19035).

The paradigm for antisense-regulated control is the *hok/sok* system of plasmid R1. Here the toxin, Hok (host killing), is also a protein but the antidote, Sok (suppression of killing), is an unstable RNA that does not directly interact with the toxin as in the proteic systems. Instead, it interacts with the *hok* message and prevents its translation. Binding of the two RNAs allows RNase III to degrade the *hok* message and thereby prevent its killing activity. In plasmid-free cells, the unstable Sok RNA is quickly depleted that allows translation of the *hok* message. The product, Hok, kills cells by damaging their membrane.

The regulation of the *hok/sok* system is entirely posttranscriptional but more intricate than that has been discussed in connection with replication control (Fig. 2). The activity of *hok* mRNA depends upon a complicated folding pathway (Fig. 6). During transcription, the 5′ end is locked into a metastable hairpin structure that sequesters a sequence required for activation of *mok* translation. Translation of Hok is coupled to that of Mok, and therefore the metastable structure prevents Hok

Fig. 6 Regulation of plasmid addiction operons. (a) In the *ccd* operon of F plasmid the antidote–toxin pair, CcdA and CcdB, also regulate the transcription of the operon. CcdA is the primary repressor. CcdB joins CcdA and helps in the repression thereby serving as a corepressor. The operon is therefore autoregulated. (b) The SegB region contains a three-gene operon in which the first gene is a dedicated autorepressor that indirectly controls the expression of the antidote–toxin pair. (c) The *hok/sok* system of plasmid R1 has three genes *mok, sok,* and *hok.* The *sok* antidote is an antisense RNA that inhibits translation of *mok* protein, the toxin. Translation of *hok* is coupled to *mok*, and therefore, the antidote RNA controls the toxin translation indirectly through *mok.* The toxin translation is actually under more complex control. Initially, the *hok* message is not translated because of the formation of a metastable structure at the beginning of the message that includes a sequence (tac) required to activate *mok* translation. The metastable structure stabilizes ucb/*mok*RBS hairpin and thereby makes *mok*RBS unavailable for translation. After a full-length transcription, a refolding takes place destabilizing the metastable hairpin, but the ucb/*mok*RBS hairpin is still maintained as the tac sequence forms a new structure that includes a hybrid with the 3′ end of the message. The 3′ end is then slowly processed that triggers refolding of the message that allows tac to hybridize with ucb, freeing the *mok*RBS for translation initiation. The refolded structure also allows hybridization with Sok RNA.

translation also. In the full-length *hok* mRNA, the metastable structure is lost but the message is refolded into a structure that is still inactive and requires processing from the 3′ end before it can be translated. However, the processed message is also the target for Sok RNA, and therefore translation is possible in plasmid-free cells. The toxin production thus requires breakdown of RNA secondary structures, refolding and processing, then translational coupling, and finally escape from Sok hybridization and RNase III attack. Avoidance of cell killing is particularly important when an addiction module is trying to establish itself in a new host. One of the



reasons for employing the delay tactics in Hok toxin synthesis may be for establishment without killing the host. These tactics will also discourage accidental toxin production in established cells.

In the restriction–modification system, the toxin is the restriction enzyme that can cleave specific sequences on DNA, and the antidote is the methylase that protects the sequences by modifying them by attaching methyl groups. The antidote thus does not directly interact with the toxin nor prevents its synthesis, but protects the target of the toxin. In the presence of the restriction–modification gene pair, nearly all, if not all, of the restriction sequences are modified. When the gene pair is lost, mere dilution of the enzymes will suffice to kill the cell and no differential stability of the toxin–antidote pair is required. This is because of the differential demand on the two enzymes. While survival would require modification of nearly all restriction sites and therefore a heavy demand on the methylase, restriction of even a single site can be potentially lethal. Although restriction–modification systems are known for almost fifty years, that they are powerful addiction systems has been realized relatively recently.

The restriction–modification genes are regulated at the level of transcription and some modules have a third gene solely for regulatory purposes as has been discussed for other types of addiction systems. When *E. coli* K12 *hsdK* genes are transferred to a new host, modification activity is observed right away but restriction activity appears about 15 min later. Such staging of expression would help establish the system in an unmodified host.

2.3.2 Addiction Systems in Chromosomes

All three types of addiction modules have been found in chromosomes, in bacteria, and, sometimes, in multiple copies in the same chromosome. Since addiction modules cannot increase the stability of the chromosomes as they do for plasmids, and since they are potentially toxic, the question arises as to why they are so prevalent in the chromosome. Their accumulation can be understood because once in, be it in the plasmid or chromosome, they would be hard to get rid of. Even then potentially harmful elements are expected to be eliminated unless they confer some benefit to the host. The restriction–modification genes can destroy invading foreign DNA thereby help maintain the genetic identity of a species. The chromosomal *mazEF* operon is induced by nutritional stress. The operon is autoregulated by the combined action of MazE and MazF antidote–toxin pair like the Ccd system (Fig. 6). Additionally, the expression of the operon is inhibited by high concentration of ppGpp, which is synthesized upon nutritional stress. Since MazE antidote is labile, its level falls rapidly that leaves MazF toxin to exert its toxicity. The dead cells not only do not compete for nutrients but they may also provide their resources to surviving siblings. Similarly in stresses like infection, precocious death of the infected population prevents the spread of the infectious agent to the uninfected population and thereby saves them. Thus, addiction modules can be viewed as stability elements for the chromosome as well. In any event, death of a subpopulation to save the majority (altruism) appears to be ubiquitous in nature.

2.4 Multimer Resolution

Formation of plasmid multimers is rather common since it is caused by homologous recombination, a highly conserved

function in bacteria. Multimerization is undesirable for plasmid maintenance as it reduces the number of segregation units. This is because plasmid replication control systems generally count origins per cell rather than number of plasmid copies. To avoid plasmid loss due to multimerization and consequent lowering of copy number, plasmids encode systems that reduce multimers to monomers by (intramolecular) site-specific recombination. The effect of multimerization must be significant since multimer resolution (MR) systems are widespread among plasmids from such as ColE1, P1, F and RK2 Gram-negative and pAM1, pIP50 and pSM19035 from Gram-positive bacteria. The presence of MR systems is easily rationalized for low copy number plasmids as further lowering of their segregation units would have a more significant effect on the production of plasmid-free cells.

Detailed study in ColE1 has revealed the requirement of the MR system even for a high copy number plasmid. Even if dimers (and higher multimers) form at a low frequency, they can become overrepresented in a fraction of the cell population. Because dimers have twice the origin number, they enjoy a higher chance of being replicated as plasmids are chosen at random for replication. Once replicated, the chance of one of the progeny dimers being selected remains high and this leads to an ever-increasing bias for dimer replication that can eventually spawn dimer-only cells (*plasmid apartheid*). Since plasmid copy number would be lowest in dimer-only cells, they would be the primary progenitor of plasmid-free cells. Plasmid apartheid can increase the probability of plasmid loss by 30 000-fold. This high loss rate due to plasmid dimerization and segregation to dimer-only cells has been called *dimer catastrophe* by Summers. The role of plasmid apartheid became evident when the proportion of dimers was correlated with the plasmid loss rate by computer modeling. In pBR322, only 4% of the plasmid DNA is found as dimers. If the dimers were assumed to be distributed randomly in the cell population, their contribution to lowering of plasmid copy number was found to be too low to account for the observed plasmid loss rate. For satisfactory accounting, about half of the dimers needed to be present in dimer-only cells and the rest as a mixture with monomers. Thus, for plasmid stability, in addition to the mean dimer copy number, it is important how the dimers are distributed in the population.

The MR system in the case of ColE1 requires two host recombinases, XerC and XerD, and a site in the plasmid, *cer*, where catalysis occurs. The system can only convert dimer to monomer and not the reverse, that is, works only intramolecularly. For this directionality of recombination, two other accessory host factors, ArgR and PepA, are required. Furthermore, the sites need to be directly repeated and the dimer needs to be supercoiled. These topological constraints make perfect sense if the MR systems have evolved to resolve dimers. A detailed molecular model has been proposed where the two *cer* sites bound by XerC, XerD, and PepA synapse via an ArgR bridge, which is too weak unless reinforced by supercoiling. This explains why the sites need to be in cis. XerC and XerD also participate in resolving chromosomal dimers that arise in about 15% of the cells in each generation. The chromosomal site is called *dif*, and instead of ArgR and PepA, the resolution of chromosomal dimers require a cell division protein FtsK. Unlike the plasmid case in which preventing cell division buys more time for recombination, the connection to cell division allows

chromosomal dimer resolution only at the time of cell division preempting the scope for any back reaction.

The MR system alone, however, is not necessarily efficient enough to eliminate the catastrophic plasmid loss due to dimerization. In ColE1, the monomerization rate is too slow compared to the rate with which dimers build up by replication. Fortunately, a regulator of cell division, *rcd*, is made only from plasmid dimers (multimers). The promoter for *rcd* maps in *cer*, and the synaptic complex formation on dimers allows proper geometry of the promoter to be active. The cell division is delayed as dimers build up. The extension of cell generation time allows more opportunities for the MR system for monomerization and this helps to minimize plasmid loss. The *rcd* in fact is a short RNA but how it interferes with cell division is not known. Interestingly, it downregulates expression of chromosomal genes but not the plasmid genes. Thus by overexpressing *rcd*, cells can be directed to make pure cloned gene products.

It remains to be seen if systems like Rcd are there to help other MR systems. In iteron-carrying plasmids, dimers are discriminated against for replication. The presence of two origins in cis allows more efficient pairing (handcuffing) of the origins that is believed to inactivate both the origins. Thus, iteron-carrying plasmids seem to have been selected to prevent rather than cure plasmid apartheid.

2.5 Incompatibility

Wild strains of bacteria often contain multiple plasmids that can be stably inherited for many generations. In *E. coli*, it has been possible to maintain eight different plasmids in the same strain at their natural copy number. In contrast, cells doubly transformed with genetically related plasmids usually fail to maintain them during growth without selection for both. These plasmids are called *incompatible* and those that can be stably maintained are called *compatible*. As pointed out by Novick and Hoppensteadt, to be incompatible the plasmids in question (1) must form a common pool on the basis of some shared determinants (due to genetic relatedness), and (2) are withdrawn at random for replication and/or partition. That plasmids are chosen at random for replication has been verified: in a cell cycle, the same plasmid can replicate more than once whereas others none at all. Plasmids with compatible replicons can also show partition-mediated incompatibility if their *par* systems are similar enough and important for stable inheritance.

Incompatibility (*inc*) due to replication can be viewed as a phenotype of plasmid negative control functions. If a plasmid pair is equally sensitive to each other's control systems, their total copy number would be characteristic of the individual plasmids but the ratio of the two plasmid kinds will vary from cell to cell because they are chosen at random for replication. Taken to the limit, this disproportion leads to loss of one or the other plasmid type, manifesting incompatibility. In compatible pairs, the control system of one does not recognize the other, and each is dedicated to maintain the copy number of the same kind. Since all plasmids control their copy number, they all exhibit incompatibility. This phenotype has been exploited in plasmid classification into separate incompatibility groups and this has proven useful in terms of understanding relatedness of control functions.

In practical terms, knowledge of incompatibility becomes necessary for designing experiments that call for maintaining multiple plasmids in the same cell. With the ease of DNA sequencing, plasmid relatedness is initially determined by direct sequence comparisons. However, point mutations in control regions can alter control specificity, making experiment-based incompatibility classification a more reliable approach.

Determinants of *inc* are conveniently identified by cloning and overexpression by their ability to destabilize the parent plasmid in trans. It should be noted that not all negative control elements exert incompatibility. Whereas all antisense RNAs are strong *inc* determinants, none of the accessory proteins like Rom of ColE1 and the Cop proteins of plasmids under antisense control are (see Sects. 2.1.2 and 2.1.3). The steady state concentration of the accessory proteins are probably saturating so that further increase of their concentration does not affect replication. It appears that, to be an *inc* determinant, the control element activity needs to be concentration sensitive near its steady state value. Gross overproduction can cause destabilization artifactually. This is another reminder that concentration sensitivity of the activity, a control element, is at the heart of measuring and correcting copy number deviations.

2.6 Cell cycle Control

Plasmids do not seem to have mechanisms to directly communicate with host cell cycle events to ensure that their replication and partition are complete before the cell division. Cross talks among the cell cycle events, chromosome replication, segregation, and cell division, are also not apparent for the host itself. For a growing culture of *E. coli*, the events occur in an orderly fashion with a periodicity of once per cell generation. However, it is clear that replication and segregation can happen independent of cell division since blockage to cell division does not prevent the other two events. It has been suggested by Boye and Nordström that the events are best viewed as independently regulated processes that run in parallel, meaning that initiation of one event does not wait for the completion of another as in biosynthetic pathways. In the latter, the product of a step serves as the substrate for the next one. If the first step is inhibited, the next one cannot start, unlike the situation in bacterial cell cycle events. How is the order of cell cycle events maintained? The suggestion is that some behind-the-scene growth-related factors regulate the cell cycle events independently and indirectly maintain their order. In the case of perturbation such as DNA damage, checkpoint controls are induced that helps to restore the order. For example, damage to DNA blocks replication fork movement that induces synthesis of an unstable cell division inhibitor. When the damage is repaired and replication elongation resumes, no new inhibitor is synthesized and cell division is no longer blocked. The communication channel in the normal course (without DNA damage) between DNA replication and cell division has not been identified. In *E. coli*, small signaling molecules cAMP and ppGpp, and in *Caulobacter crescentus* the CtrA protein, which control several events are best candidates for cell cycle regulators at the moment.

Plasmid replication does not depend on plasmid segregation. The *par* genes can

be deleted without affecting replication. This is best evident in integrative suppression experiments in which defects in host replication initiation are suppressed efficiently by integrating a plasmid replicon in the chromosome. This process remains unchanged whether or not *par* genes are present. On the contrary, it is believed that plasmid and chromosome segregation are facilitated by replication. We have discussed earlier the possibility that replication can unclump plasmids and thereby help in their segregation (see Sect. 2.2). Chromosomal replication has also been implicated in disposing daughter DNAs to opposite cell poles and thereby their segregation. In P1, cell division may trigger plasmid segregation (see Sect. 2.2.3).

Plasmid replication and segregation appear to be unlinked to their chromosomal counterparts. Plasmids have to adjust for copy number fluctuations constantly. A cell-cycle-specific unique timing of replication almost surely cannot apply for plasmids. Helmstetter and coworkers have studied replication of several plasmids, and none has shown cell-cycle-specific timing of initiation under conditions the chromosomal origin did. It should be noted that evidence for cell-cycle-specific replication, even if found, could be a side effect of replication control. For instance, if the plasmid such as P1 has a very low copy number and a replication control that senses a threshold concentration of initiators, then all cells will replicate their plasmids at the same time in the cell cycle, even if there is no explicit dependence on cell cycle events (the same idea proposed by Boye and Nordstrom). Genes such as *mukB* that help chromosome segregation by condensing the DNA do not affect plasmid segregation. Overall, the cell cycle connections remain tenuous and will remain so until specific regulators like CtrA are identified.

3 Horizontal Spread

Plasmids not only move vertically but also horizontally. The horizontal spread is easily rationalized for its potential for gene transfer across species and genera, thereby contributing to bacterial fitness and evolution. Some plasmids can have unusually broad host range (BHR) for extrachromosomal existence, and potentially even a broader range of recipient hosts in which they can be transferred by conjugation. Even if the plasmid cannot replicate in a new host, the DNA can be cleaved and recombined into the host chromosome. A BHR plasmid, RK2, has been established in forty species of Gram-negative bacteria. Plasmid F has been transferred from *E. coli* to yeast, RK2 from *E. coli* to cultured mammalian cells, and a segment (T-DNA) of Ti plasmid is transferred naturally from *Agrobacterium* to the nucleus of plant cells, demonstrating the capacity of horizontal gene transfer (HGT) between genera and kingdoms. The magnitude of HGT among microbes, as revealed by genome sequencing, has been startling. As many as 40 genes have been found to be shared exclusively by bacteria and human, that is, without any occurrence in invertebrates. Since the year 2000, four textbooks have appeared on HGT (also called LGT, L for lateral) that speaks for the current interest on this subject (Mobile DNA II, ASM Press; Horizontal Gene Transfer, Academic Press; Lateral DNA Transfer, CSHL Press; and Horizontal Gene Pool, Harwood Academic Publishers).

3.1 Conjugation

The primary mechanism for HGT is conjugation. The transfer of DNA requires more elaborate machinery than their maintenance functions discussed above and can involve even up to 50 plasmid-encoded genes, usually called *tra*. Unlike vertical movement where plasmids capitalize on host cell division machinery, HGT requires cell-to-cell contact (mating pair formation), synthesis of an extra strand of DNA specifically for transfer and transporting DNA across the donor and recipient membrane barriers through a mating pore. Finally, survival of the transferred DNA in the new host environment must have entered in the selection process during evolution of conjugative systems. These steps of conjugation are highly conserved whether the transfer is between bacteria or that between bacteria and eukaryotic cells.

3.1.1 Mechanisms of DNA Transfer

In Gram-negative bacteria, the mating pair formation requires building a special apparatus, pilus, which is a tube like extracellular structure whose role is to reach out and touch the recipient and bring about cell–cell contact by pilus retraction (by depolymerization of pilin subunits). In Gram-positive bacteria, cell–cell contact is mediated not by pili but by plasmid-encoded aggregating substances that are secreted in response to pheromones secreted by plasmid-free recipients. The cell–cell contact is believed to send a signal to the donor to form a mating pore through which the DNA is transferred. The conjugative proteins that form the pore belong to the type IV secretion systems, a widely used system to transport protein across bacterial membranes. DNA synthesis for transfer is well understood and requires an enzyme relaxase (nickase) that cleaves one strand of *oriT* (origin of transfer). The free 3′-OH of the nick serves as the primer for rolling circle replication. The replication steps are grossly similar to what has been described for pT181 (see Fig. 3; Sect. 2.1.3). The relaxase remains covalently bound to the 5′end, which is guided through the mating pore into the recipient and brings with it the attached single-strand as it is being released by replication. This process continues until the entire plasmid has been regenerated in the donor and a complete strand is transferred to the recipient. According to de la Cruz and colleagues, conjugation is a union of two basic processes: rolling circle replication and protein transport, helped by a coupling protein that guides the entry of the relaxase (pilot protein) into the protein transport machinery (mating pore/type IV secretion system).

3.1.2 Establishment of Transferred DNA

Establishment of the transferred strand in the recipient cell requires first the strand to be circularized. The relaxase covalently bound to the leading (5′) end of the transferred strand does this job. The 3′end most likely extends beyond one full length of the plasmid regenerating the *nic* site. The 5′-bound relaxase recognizes this site and by a cleavage–joining reaction regenerates a monomer circle. The next step is synthesis of the complementary strand. The synthesis would require multiple initiations as in any lagging strand synthesis and seems to be aided by plasmid-encoded primases that are transferred along with DNA to recipient. There are several safeguards to protect the transferred DNA in the recipient from attack by nucleases. The relaxase could be protecting the 5′-end from exonucleases. The lagging strand is most likely

synthesized as it enters the recipient. The conversion to double-stranded DNA could provide stability to inherently less stable single-stranded DNA and repair possibilities in case of strand breakage. Some plasmids have genes for SSB (single-strand binding) and PsiB proteins. The latter can prevent SOS response. Both the genes are transferred early and induced in the recipient during conjugation. SSB can protect single-stranded DNA and is known to facilitate many DNA metabolic processes, including replication. PsiB may interfere with RecA binding to single-stranded DNA and thereby speed up their conversion to double strand. Another early transferred gene is *ardA* whose role possibly is to protect the unmodified DNA from host restriction.

3.1.3 Regulation of Transfer

It is natural that a complex and energy-consuming process like conjugation will be highly regulated. The transfer genes are normally kept repressed (fertility inhibition), and both extra- and intracellular signals are involved in induction of the transfer process. Apparently, a balance is struck to minimize metabolic burden on the host and make the transfer an efficient process. Considerable details on regulation are known for plasmids like F, RP4/RK2, *Enterococcal* plasmid pAD1 and *Agrobacterium* plasmid Ti. It is also clear that the network of *tra* control coordinates with other plasmid processes like vegetative replication. Conjugative plasmids encode genes, which are expressed in the recipient at the completion of transfer to prevent a second bacterium to transfer the same or closely related plasmid. This requires coating the outer membrane of the recipient with plasmid encoded proteins or lipoproteins that discourage mating pair formation. Avoiding wasteful transfers also prevents cell lysis that may occur if donors outnumber the recipient and the conditions permit intense mating.

When the entire machinery for conjugation is encoded by plasmids themselves, they are called *self-transmissible*. There are also plasmids that only encode the requirements to initiate rolling circle replication (*oriT,* relaxase and a few accessory factors). These are called mobilizable plasmids, and a coresident self-transmissible plasmid is required for mating pair formation and transfer. Plasmids without any *tra* gene can also be mobilized if they can hop into a self-transmissible plasmid by transposon or other jumping genes (IS elements) or by homologous recombination. When F plasmid integrates with the *E. coli* chromosome, it can mobilize the entire 4.7 Mb of chromosomal DNA into a recipient indicating the efficiency and processivity of the conjugative process. This may require pushing DNA though the mating pore by a motor protein, as is the case in chromosome segregation at cell division by FtsK and during sporulation by SpoIIIE.

Horizontal transfer can also be considered a strategy for hereditary stability. In principle, a plasmid can be conjugated to multiple recipients and thereby outpace the rate of plasmid spread over cell growth rate. Although the transfer is tightly repressed and normally rare, plasmids in the recipient cells (exconjugants) remain derepressed transiently and this may allow further transfer to plasmid-free recipients. Thus, HGT can be considered an alternate means of plasmid maintenance. HGT should not affect plasmid maintenance by vertical transmission since transfer is tied to a new round of replication that should leave the plasmid copy number intact.

3.2 Broad Host Range

Although a plasmid can explore and establish in an unrelated bacterial species by conjugative transfer, its maintenance in the plasmid state requires, most importantly, vegetative replication. Several plasmids seem to have acquired this capability by minor adaptation of the mechanisms that maintain the narrow range plasmids. The adaptation has taken place in multiple ways that either results in changes in origin sequences, or in the plasmid-encoded initiator protein, in acquisition of multiple replicons in the same plasmid or in reduced dependence on host functions.

In one of the best-studied BHR plasmids, RK2, an iteron-type plasmid belonging to IncP group, a 35-bp insertion in the minimal origin inactivates the origin activity in *E. coli* and in *Pseudomonas putida* but not in *Pseudomonas aeruginosa*. In a different BHR plasmid, R1162, the minimal origin for replication in *E. coli* needs to be extended for replication in *P. putida*. It appears that one strategy to broaden plasmid host range is to increase the origin information content. The initiator protein of RK2, TrfA, also appears to have dispensable information for replication in some hosts that may become essential in some other hosts. The protein is made both as full length, TrfA-44, and as a smaller version, TrfA-33, from an internal in-frame translational start site. Although the smaller initiator suffices in many Gram-negative bacteria, the full-length protein is essential for replication in *P. aeruginosa*.

The understanding for the requirement for the larger TrfA-44 for replication in *P. aeruginosa* was greatly aided from studies *in vitro*. A crucial requirement for initiation of replication for any replicon is the loading of a replicative helicase. Replicons use a variety of mechanisms for this purpose. At the chromosomal origin of *E. coli*, the helicase DnaB loading requires both the host initiator DnaA and the helicase loader DnaC. DnaA interacts with origin DNA as well as DnaB but its transfer to origin strands requires DnaC. DnaA also binds to many plasmid origins including RK2 and apparently plays a similar role in loading of DnaB. However, TrfA-44 can load DnaB directly in *P. aeruginosa* without requiring DnaA and DnaC. It appears that the N-terminal part of TrfA-44 that is missing in TrfA-33 plays the role of both inviting DnaB to RK2 origin (normally the role of DnaA) and unloading of DnaB (normally the role of DnaC). As expected, DnaA-binding sites are not required for RK2 replication in *P. aeruginosa*. However, for loading of DnaB to RK2 origin in *E. coli*, both TrfA-44 and TrfA-33 still requires DnaA and DnaC. A better understanding of these results would require actual affinity measurements of various DNA–protein and protein–protein interactions. For example, TrfA-44 interaction with DnaB may be reversible enough to obviate the need for DnaC in *P. aeruginosa*.

Some BHR plasmids like RSF1010 (belonging to IncQ group) have opted to play safe by encoding both the plasmid-origin-specific initiator and the helicase so that the uncertainty of proper interfacing of the two is avoided in a new host. In *E. coli*, the DnaB helicase interacts with the DnaG primase and recruits it to the origin for the priming of DNA replication. Since RSF1010 makes its own helicase, it is in order that the plasmid also makes its own primase to ensure helicase–primase compatibility. These plasmids by not requiring DnaA, DnaB, DnaC, and DnaG can replicate in a wide variety of hosts including some Gram-positive bacteria.

The presence of more than one replicon in the same plasmid is a common occurrence (e.g. F, P1, R6K, pCU1) and in some cases (pCU1 belonging to IncN group) helps to extend the host range. Host-specific replicons have also been combined in the laboratory (called shuttle vectors) that replicate efficiently in both of their natural hosts. This provides the proof of principle that combining replicons is a feasible strategy to extend host range. A narrow host range plasmid can extend its host range by forming a cointegrate with a BHR plasmid. The alternate replicons, even if they do not increase the host range, can serve as back-up replicons in case the primary replicon fails to function and thereby contribute to plasmid stability.

An independent approach to study the basis of BHR has been to start with a narrow host range plasmid and extend the host range by mutation. Characterization of the mutants may then identify the relevant basis. It is clear that improving interactions between the plasmid-specific initiator and the host initiator improves the replication success in a new host. Plasmid pPS10 replicates efficiently in *P. aeruginosa* and in *P. putida* but not in *E. coli*. The inability to replicate in *E. coli* was overcome by mutating either the plasmid initiator RepA or the host initiator DnaA, implying that RepA–DnaA interaction was not optimal in *E. coli* for helicase loading. Since DnaA initiates the chain of events involving other replication proteins (DnaB, DnaC, DnaG etc.), once the plasmid initiator can interact with DnaA, the interactions with rest of the host proteins should follow automatically. It may seem that the adaptation in a new host may minimally require the ability to recruit DnaA to the plasmid origin. However, the two most promiscuous plasmids known to date, RK2 and RSF1010, have adopted strategies for independence from DnaA altogether for helicase loading.

Efficient maintenance would require that the replication be controlled and other maintenance functions like partition are operative. The BHR plasmids described above mostly belong to the iteron family of plasmids where genetic requirements for initiation and its control are the same. Control of replication will automatically follow with replication success. BHR plasmids also employ antisense RNA and/or a separate repressor protein for controlling copy number. Examples include several plasmids of Gram-positive origin such as pMV158, a *Streptococcal* plasmid and pC194, a *Staphylococcal* plasmid that can replicate even in a Gram-negative bacterium, *E. coli*. Extension of host range from Gram-positive to Gram-negative has also been obtained by mutating plasmids. The host range of maintenance functions other than replication is less known except that chromosomal *par* system of Gram-positive *B. subtilis* and Gram-negative *P. putida* stabilize a partition defective F plasmid in *E. coli*. The host range of other maintenance functions are likely to be broad as their requirement for BHR plasmids is expected to be as important as they are for the narrow host range plasmids.

3.3 Bacterial Evolution

A particularly striking discovery from genomic sequencing is the degree of occurrence of horizontal (lateral) gene transfer (HGT) among microorganisms. HGT is now recognized to be a major force in shaping microbial genomes and enhancing genetic diversity and adaptation in bacteria. For instance, there is more than 20%

difference in the genetic make up between two strains of *E*. coli (pathogen O157:H7 vs benign K12). Much of this difference (speciation) can be explained by gene acquisition and loss by HGT. Plasmids and other mobile genetic elements offer blocks of DNA (an extreme example being the transfer of entire bacterial chromosome by conjugation) that appear to have accelerated bacterial adaptation and evolution much more than what would have been possible with point mutation and selection. Within a brief span of seven years, diverse strains of nonsymbiotic rhizobia were found to have acquired symbiotic genes by HGT in the environment. One reason for fast plasmid-mediated adaptation is because plasmids can replicate faster than the host by spreading laterally to cells that lack them (conjugative transfer always involves an extra round of replication so that the donor plasmid remains in the donor cell). Currently, there is great interest in the studies of bacterial population genetics and evolution and on the role of mobile genetic elements in maintaining bacterial diversity and adaptation.

3.4 Impact on Public Health

Although understanding the mechanisms of BHR is mechanistically challenging, and cloning vectors based on BHR plasmids are boon to the burgeoning field of research in non–*E. coli* bacteria, the plasmids are potentially the most dangerous for spreading genes undesirable for human health. Usually genes conferring resistance to a variety of antibiotics and toxic heavy metals, and encoding virulence factors are found in mobile genetic elements such as plasmids, transposons, and bacteriophages, not in the host chromosome. Plasmid-borne virulence factors are found to be involved in a wide variety of functions such as adhesion, host cell penetration and invasiveness, high-affinity iron transport, and diseases caused by a bacterial toxins including anthrax, tetanus, diarrhea (due to labile toxin, LT) and food poisoning (due to enterotoxin D). However, by far, the biggest impact on public health has been the rapid spread of antibiotic resistance bacteria in the environment. Every class of antibiotics has developed resistance within a year to a decade of clinical use. In the United States, resistance to *Streptococcus pneumoniae* to two commonly prescribed antibiotics is predicted to reach 40% by July 2004. Antibiotics resistance is therefore not a matter of if but when. The widespread use of antibiotics is the cause of selection for this high rate of resistance. The problem is compounded by the presence of several resistance genes in the same plasmid or other mobile genetic elements, and consequently, in the selection of multidrug resistance bacteria that can resist all available antibiotics. Normally, transposable elements are the primary source of resistance genes. The much-studied conjugative plasmid R1(also called R100/NR1, see Sect. 2.1.3), isolated in late 1950s, was found to carry genes for resistance to chloramphenicol, fusidic acid, spectinomycin, streptomycin, sulfonamide, and tetracycline primarily due to transposon hops. Time has come to explore alternates to antibiotics to treat bacterial infections, and fundamental research in plasmid will obviously guide the future line of research on topics such as on how to avert conjugal transfer, which is presently thought to be the major means of transfer of antibiotic–resistance determinants in the environment.

4 Concluding Remarks

Using a few well-studied systems, the article tries to present our current thinking on how plasmids are maintained and has only touched upon other facets of plasmid research such as public health, and bacterial diversity and adaptation. The emphasis has been on mechanisms. Use of plasmid as research tools and in biotechnology have not been discussed. These topics deserve to be covered in separate articles.

4.1 As Model Chromosomes

Because of their small size and dispensable nature, plasmids appeared attractive as models for studying chromosome maintenance in the 1970s. It was certainly logical to expect that the issues involved would be similar. However, it turns out that the *E. coli* chromosome is regulated differently from its plasmids. The cell can tolerate about 30 extra copies of its origin whereas plasmid replication essentially stops with a two-fold increase of copy number. To date also no chromosomal centromere has been found in *E. coli*, suggesting that the chromosome segregates differently from plasmids. Hopefully, emerging interest in non–*E. coli* systems will permit generalization on maintenance functions in the bacterial world.

Plasmids need to regulate its replication independent from that of the host. Since plasmids need to adjust the rate of replication to correct for fluctuations in copy number, it cannot afford to follow once per cell cycle replication characteristic of the host chromosome. This requirement for independence from the host appears sufficient to justify encoding of replication control functions in plasmids without exception. The structure of iteron-mediated plasmids does give the impression that its origin has evolved from the host origin by incorporating plasmid-specific control elements, the iterons. Although plasmid *par* genes are found in the chromosome of several non–*E. coli* bacteria such as *Bacillus subtilis*, *Vibrio cholerae*, *Pseudomonas putida*, and *Caulobacter crescentus*, it remains to be seen whether the mechanisms are similar. It is already evident that because chromosome partition has to deal with a much larger piece of DNA, additional requirements are there for chromosome condensation, which can be dispensed with for plasmids. The *par* genes are essential in *Caulobacter crescentus* suggesting that the genes might serve additional functions. Genetic requirements for dimer resolution also are different for the ColE1 plasmid and the *E. coli* chromosome. The plasmid maintenance function that was least expected in the chromosome, the toxin-antidote system, however, is found in multiple copies in the chromosome (see Sect. 2.3.2). It seems that the common ground is likely to widen as our knowledge of plasmids and chromosomes progress.

4.2 Contributions
